Nanoparticle formulations designed and developed by Y.O.

Conflict of interest: The authors have declared that no conflict of interest exists.
Abstract:
The mortality of patients suffering from acute myocardial infarction (AMI) is linearly related to the infarct size. As regeneration of cardiomyocytes from cardiac progenitor cells is minimal in the mammalian adult heart, we have explored a new therapeutic approach which leverages the capacity of nanomaterials to release chemicals over time to promote myocardial protection and infarct size reduction. Initial screening identified two chemicals, FGF1 and CHIR99021 (a Wnt1 agonist/GSK-3β antagonist) which synergistically enhance cardiomyocyte cell cycle in vitro. Poly-lactic-co-glycolic acid (PLGA) nanoparticles (NP) formulated with CHIR99021 and FGF1 (CHIR+FGF1-NPs) provided an effective slow release system for up to 4 weeks. Intramyocardial injection of CHIR+FGF1-NPs enabled myocardial protection via reducing infarct size by 20-30% in mouse or pig models of postinfarction LV remodeling. This LV structural improvement was accompanied by a significant preservation of cardiac contractile function. Further investigation revealed that CHIR+FGF1-NPs resulted in a significant reduction of cardiomyocyte apoptosis and increase of angiogenesis. Thus, using a combination of chemicals and a NP-based prolonged release system that work synergistically, this study demonstrates a novel therapy for LV infarct size reduction in hearts with acute myocardial infarction.
Introduction

The mortality of patients suffering from acute myocardial infarction (AMI) is linearly related to the infarct size. As cardiomyocyte regeneration from cardiac progenitor cells is minimal in the mammalian adult heart, salvaging the myocytes that are otherwise destined to die remains the most important objective in cardiovascular sciences. In response to a prolonged coronary artery occlusion, the distal myocardial myocytes undergo membrane rupture followed by release of their intracellular enzymes into the extracellular space. If we assume that AMI is a heterogeneously damaged tissue, then to discover the interventions sparing the border zone myocytes that have been less severely damaged could effectively reduce the infarct size and save lives. Nanoparticles (NPs) can act as sustained release delivery vehicles for growth factors and small molecules for an enhanced myocardial recovery in ischemic heart diseases (1, 2). Fibroblast growth factor 1- (FGF1) is one of these factors and it has been shown that intramyocardial injection of FGF1-loaded poly (lactic-co-glycolic acid) (PLGA) microparticles into infarcted areas improved angiogenesis and/or arteriogenesis, as well as ejection fraction (EF)(3). CHIR99021 (CHIR) is an aminopyrimidine derivative that functions as a Wnt (Wingless/Integrated) signaling activator. CHIR-loaded NPs efficiently direct reprogramming of fibroblasts into functional cardiac myocytes and might thus be endowed with a therapeutic potential in cardiovascular regeneration(4). In vitro study of screening of chemicals that enhance cardiomyocyte cell cycle, we have identified the doses and the combination of CHIR and FGF that are most effective in promoting the cell cycle and anti-apoptosis. Using LV postinfarction remodeling models of mouse AMI or pig ischemia reperfusion (IR) injury, we have then investigated whether the combination of NPs with both CHIR and FGF1, can synergistically protect ischemia-threatened cardiomyocytes from apoptosis, accelerate angiogenesis through promoting the proliferation of endothelial and vascular smooth muscle cells, and consequently enhance myocardial protection. The findings demonstrate that a controlled release formulation of PLGA NPs encapsulated with CHIR+FGF1 exerted significant myocardial protective effects, and represents a potential novel strategy for improving post-ischemic myocardial protection.
Results

Identification of chemicals that promote cell cycle activity of hiPS-CMs

Using the BrdU incorporation assay, we screened several different chemicals for their capacity to enhance the cell cycle activity of cultured hiPSC-CMs. We picked up hiPSC-CMs because they are easy to handle, and represent a practical system for drug testing and screening(5). These chemicals included Ly294002 (PI3 kinase inhibitor)(6), fibroblast growth factor 1 (FGF1)(6, 7), SB203580 and VX702 (p38 MAPK inhibitors)(6), KN93 (Ca2+/calmodulin-dependent protein kinase II inhibitor)(8), Su1498 (Flk-1 inhibitor)(8), and CHIR99021 (Wnt activator and GSK3α and 3β inhibitor)(8, 9). We found a combination of 5µM CHIR99021 and 100ng/mL FGF1 is the most potent treatment to induce cell cycle in hiPSC-derived cardiomyocytes (Supplemental Figure 1).

Characterization of CHIR-FGF1-NPs

We have previously shown that PLGA nanoparticles can be used as a platform for slow release (up to 4 weeks) of chemicals to the injured animal hearts and that they provide cardioprotection(2). In order to characterize the long term cardioprotective function of FGF/CHIR combination in vivo, we formulated the PLGA nanoparticles with these two factors. The size of PLGA NPs was measured using scanning electron microscopy (SEM), for both CHIR99021- or FGF1-loaded NPs (Supplemental Figure 2A and 2B). Quantification of particle diameter for CHIR-NPs (Supplemental Figure 2C) and FGF1-NPs (Supplemental Figure 2D) yielded values of 123.63 ± 44.48 nm and 129.57 ± 45.94 nm, respectively. The size and shape of CHIR-NPs and FGF1-NPs were uniform. The encapsulation efficiency of CHIR-NPs and FGF1-NPs, [i.e., \((\text{the amount encapsulated / total amount available}) \times 100\%\)], was 50.41% and 62.8 ± 1.6%, respectively. The concentration of encapsulated CHIR and FGF1 was 8.07 µg/mg and 1.26 ± 0.03 µg/mg, respectively.

Determination of release kinetics of CHIR- or FGF-1-loaded NPs as a function of time, using either nanodrop via UV/Vis spec (for CHIR) or ELISA (for FGF1), and the cumulative percentage of CHIR or FGF1 released from NPs are shown in Supplemental Figure 2 (Panels E and F). When 1000 µg of CHIR- or FGF1-loaded NPs were incubated in 1000 µl of DPBS, pH 7.4 at 37°C, 55% of the encapsulated CHIR were released during the first day and 85%, by day 15 (Supplemental Figure 2E). In contrast, 55% of the encapsulated FGF1 was released during the initial 3 days and 63% was released by day 10. Notably, between day 1 and day 30, the release kinetics strictly followed the Korsmeyer-Peppas model for FGF1-NPs (Supplemental Figure 2F). Fitting this model, \(\frac{C_t}{C_0} = k t^n\), where \(C_t\) = concentration at time \(t\); \(C_0\) = equilibrium concentration; \(k\) = drug release rate constant and \(n\) = diffusion exponent, yielded \(n = 0.123\) and \(k = 0.324\). Next, we investigated the cellular uptake and biodistribution of engineered NPs in both human umbilical vein endothelial cells (HUVECs) and human vascular smooth muscle cells (HVSMCs) in vitro by fluorescence microscopy. The endothelial (red, CD31) and smooth muscle (red, SM22α) cells were able to consistently uptake and internalize the engineered NPs (Supplemental Figure 2G and 2H).
Lastly, we explored the localization and tracing of engineered NPs in vivo, using a LAD-ligation mouse. Following LAD-ligation, the coumarin-6-loaded NPs (33.3 µg/µL NPs) were injected into the infarcted mouse heart, at 3 different sites. After 24 hours, the whole heart was removed, and the left ventricular border zone tissue sections were subjected to dual immunostaining by antibodies targeting a cardiac-specific regulatory protein, cardiac troponin T (red, cTnT), and an endothelium-associated protein, Pecam-1/CD31 (white, CD31). Fluorescent microscopic analysis revealed localization and distribution of NPs (green, NPs) within the ventricular tissue, mainly located around the infarct border zone (Supplemental Figure 2I and 2J). We further studied if NPs were preferentially taken up by different cells. We mixed HUVECs, SMCs, hiPSC-CMs and fibroblasts at the ratio of 1:1:1:1, and treated with coumarin-6-loaded nanoparticles (2 µg/ml) for 24 hours. Our data suggested that there was no preferential uptake by different cells (Supplemental Figure 2K).

Cardioprotection of CHIR+FGF1-NPs in a mouse model of MI

Left ventricular function was echocardiographically assessed before MI induction (baseline, pre-S) and again 28 days post MI (post-S) (Figure 1A). Parameters of LV function included LVEF (Figure 1B), FS (Figure 1C), ESD and EDD (Figure 1D and 1E, respectively). On day 28 post-MI, CHIR+FGF1-NPs-treated hearts presented significantly higher contractile indices (EF and FS) and smaller LV dimensions than those of the other treatment groups (Figure 1B and 1C). These functional data were corroborated by a significant reduction in infarct size in the CHIR+FGF1-NPs treatment group (Figure 1F and 1G) compared with the other ones.

We further assessed the compensatory hypertrophy around the peri-infarct border zone. Twenty-eight days after the infarct, LV hypertrophy was assessed in this area by quantifying cardiomyocyte cross-sectioning area (Supplemental Figure 3A). The MI and NP-treated groups showed significantly higher myocyte cross-sectional areas compared with sham-operated animals. Conversely, the myocyte cross-sectional area was significantly lower in the CHIR+FGF1-NPs treatment group compared with the other treatment groups (Supplemental Figure 3B). The heart weight to body weight (HW/BW) ratio of CHIR+FGF1-NPs treated animals was significantly lower compared with other treatment and MI-untreated animals (Supplemental Figure 3C).

To study if prolonged release is necessary for the observed cardioprotection, we also tried intramyocardial injection of those chemicals immediately after LAD ligation procedure. All animals were assessed 4 weeks after treatment. Interestingly, we did not observe a similar cardioprotection following a direct intramyocardial injection of free chemicals CHIR +/- FGF1 (Figure 2A-2E), i.e., cardiac function (Figure 2A-2C) and infarct size (Figure 2D-2E) between MI-only and MI plus chemical-treated mice were not significantly different. These data suggest that a prolonged release of these chemicals is important for them to exert their cardioprotective effects.

Assessment of nanoparticle-induced cardiomyocyte proliferation and apoptosis in MI mice

To probe the cellular mechanisms whereby the CHIR-FGF1-NPs mediated cardioprotection, we determined the cardiomyocyte cell cycle in infarcted hearts. To our surprise, cardiomyocyte cell cycle was negligible in either non-treated or CHIR-FGF1-
NPs-treated hearts (Data not shown), which is in contrast to our observation that these nanoparticles promote cell cycle in cultured hiPSC-CMs (Supplemental Figure 1). These data suggest that cell cycle regulation may be different between humans and lower mammalian hearts.

CHIR is well-known for its function in promoting cardiomyocyte differentiation(10). To our knowledge, there is no report about the effects of CHIR on cardiomyocyte apoptosis. However, FGF1 is well known for protecting cardiomyocyte from apoptosis(11). Therefore, we assessed cardiomyocyte apoptosis in the peri-infarct border zone. To this end, ventricular sections in this area were subjected to TUNEL assay 3 days after the infarct. At this time point, the combined CHIR+FGF1-NPs group was associated with a significantly lower number of apoptotic cells compared with all other (treated and control) groups (Figure 3A-3B), suggesting the synergistic effects of CHIR and FGF1 in cardiac cell sparing.

Assessment of nanoparticle-mediated neo-angiogenic response in MI mice

The peri-infarct border zones were evaluated for NP-induced neo-angiogenesis by dual immunostaining, using both endothelial and smooth muscle phenotypic markers, i.e., isolectin B4 (red, IB4) and SM22-alpha (green, SM22α) (Figure 4A). The CHIR+FGF1-NP-treated group showed significantly elevated vessel and arterial density compared with the other NP-treated and untreated MI groups. In this combined group, vascular densities were not significantly different from those of sham-operated mice (Figure 4B and 4C). Next, we tried to understand how these CHIR-FGF1-NPs promote angiogenesis in the infarcted mouse hearts. The pro-cell cycle activity effects of these nanoparticles in hiPSC-CMs inspired us to hypothesize that similar effects may exist in vascular cells (ECs). Indeed, we observed increased cell cycle activity of ECs (Figure 4D-4G).

Cardioprotection of CHIR+FGF1-NPs in a pig model of ischemia-reperfusion (IR) injury

We extended this study to a preclinical large animal - the pig I/R model (60-minute ligation of LAD followed by reflow). Cardiac MRI showed that by day 28 after the ischemic insult, hearts that had received NPs loaded with the two growth factors (CHIR and FGF1) exhibited greater reductions in infarct size and greater improvements in functional indices than untreated controls only subjected to I/R (Figure 5A-5G). At the same time point, the treated group showed a significant reduction in wall thickness compared with healthy controls. However, it was significant increased when compared to I/R animals. (Figure 5H-5J).

We also assessed the compensatory hypertrophy in the peri-infarct border zone. At 28 days after the infarct, the IR and NP-treated groups had significantly greater myocyte cross-sectional areas compared to those of control animals but this hypertrophy marker was significantly reduced after CHIR+FGF1-NPs treatment compared with the untreated IR group (Figure 6A-6B). The LV weight to body weight (LWW/BW) ratio was also significantly lower in the treated group (Figure 6C).

Next, we evaluated cardiomyocyte cell cycle and apoptosis in I/R pig hearts. Similar to our observations in the mouse model, no significant pro-cell cycle potential was
observed in the I/R pig model (Figure 6D-6G). In IZ and BZ, CHIR+FGF1-NPs treatment resulted in a significantly smaller number of TUNEL-positive cells compared with the IR group, although apoptosis was still significantly higher than in healthy controls (Figure 6H-6J). No significant difference in TUNEL-positive cells was observed between the different groups in the RZ (Figure 6K).

We also determined the angiogenesis response following nanoparticle treatment in I/R injury pigs. In post IR, day 28 LV sections, immunolocalization of cardiac myocyte, endothelial, and smooth muscle-specific phenotypic markers (Figure 7A) was used to assess angiogenesis in the infarct- (Figure 7B-7C), border- (Figure 7D-7E), and remote- (Figure 7F-7G) zones. In the IZ, both the numbers of IB4-positive vessel structures and of IB4-/SM22α-positive arterial structures were significantly higher than in untreated I/R animals but still lower than in healthy controls. In the BZ, the vascular densities were comparable between CHIR+FGF1-NPs treatment and control groups, and higher than in the untreated IR. In the RZ, no significant difference in vascular densities was observed between groups. Quantification of the percentage of IB4-positive cardiac microvascular endothelial cells revealed that the expression levels of both Ki-67 and PH3 were significantly higher in the CHIR+FGF1-NPs treatment group compared with the untreated IR and control groups (Figure 7H-7J).

**Treatment with CHIR+FGF1 enhances cell cycle progression of vascular cells in vitro**

To study the mechanisms underlying these chemical-mediated cardioprotection, we used an in vitro cell culture system and treated neonatal cardiomyocytes (NCMs), and the vascular cells (ECs and SMCs) with CHIR-FGF1-NPs. In order to examine the effect of CHIR and/or FGF1 on the activation and proliferation of NCMs, the synchronized in vitro NCMs cultures were treated with CHIR (5 µM), FGF1 (100 ng/ml), or CHIR+FGF1 (5 µM, 100 ng/ml, respectively) for 24 hours, and evaluated by immunostaining and fluorescence microscopy for the incorporation patterns of BrdU (Supplemental Figure 4A). Quantification of the percentage of MF20-positive (red, MF20) NCMs incorporating BrdU (green, BrdU) revealed no significant difference between the various treatments groups, i.e., CHIR, FGF1, and CHIR+FGF1 compared to control group (Supplemental Figure 4B).

To determine the effect of CHIR and/or FGF1 on the cell cycle progression of HUVECs, the cell cycle synchronized in vitro HUVEC cultures were treated with CHIR (5 µM), FGF1 (100 ng/ml), or CHIR+FGF1 (5 µM, 100 ng/ml, respectively) for 24 hours and assessed again for various cell cycle-associated markers, such as a proliferation-related nuclear protein, Ki-67 (interphase), a phosphorylated histone H3, PH3 (M phase marker), BrdU (S phase), and Aurora B (cytokinesis). The expression pattern of Ki67, BrdU, PH3, and Aurora B kinase is shown in Supplemental Figure 5A-5D. Quantification of the percentage of CD31-positive (red, CD31) HUVECs demonstrated that the expression levels of all four markers were significantly higher in the CHIR+FGF1-treated group compared with either treatment alone (CHIR or FGF1) or control groups (Supplemental Figure 5E-5H). Subsequently, to determine the effect of CHIR and/or FGF1 on the activation and proliferation of HVSMCs, the synchronized in vitro HVSMC cultures were treated with CHIR (5 µM), FGF1 (100 ng/ml), or CHIR+FGF1 (5 µM, 100 ng/ml, respectively) for 24 hours, and similarly assessed by immunostaining and f
fluorescence microscopy for the incorporation of Brdu and the expression patterns of Ki-67 and PH3 (Supplemental Figure 6A-6C). Quantification of the percentage of smooth muscle protein 22-alpha-positive (red, SM22α) HVSMCs indicated that the incorporation of Brdu and the expression patterns of Ki-67 and PH3 were significantly greater in the combined treatment group compared with either treatment alone (CHIR or FGF1) or control groups (Supplemental Figure 6D-6F).

To determine the effect of CHIR and FGF1 on the cell cycle progression of fibroblasts, the porcine cardiac fibroblasts were isolated, cultured, cell cycle synchronized and treated with CHIR+FGF1 (5 µM, 100 ng/ml, respectively) for 24 hours and assessed again for various cell cycle-associated markers, including BrdU (S phase) and phosphorylated histone H3, PH3 (M phase marker). The incorporation of BrdU and the expression pattern of PH3 are shown in Supplemental Figure 7A-7B. Quantification of the percentage of vimentin-positive (red, vimentin) fibroblasts demonstrated that the expression levels of all two markers were significantly higher in the CHIR+FGF1-treated group compared with control groups (Supplemental Figure 7A-7B).

Global transcriptome profiling of CHIR+FGF1-treated HUVECs by RNA-seq

Total cellular RNA was isolated from CHIR+FGF1 (5 µM, 100 ng/ml, respectively)-treated and control HUVECs and subjected to next generation RNA sequencing (RNA-Seq). The mRNA profiles indicated that 815 genes out of 18845 genes (adjusted \( p < 0.05 \)) showed significant changes in their expression levels. The relative mRNA expression profile of various representative genes related to angiogenesis, cell proliferation, cell senescence and death is shown in Supplemental Figure 8 A. Furthermore, qPCR validation of RNA-Seq data confirmed that cyclin D1, CDK1, CDK4, and cMyc were significantly upregulated in CHIR+FGF1 treatment groups compared with the other treatment and control groups (Supplemental Figure 8B). Conversely, cyclin D2 was significantly downregulated in all treatment groups compared with the controls (Supplemental Figure 8B).

Similarly, the total cellular protein was extracted from the synchronized HUVEC cultures, i.e., control cells and cells that were exposed to CHIR (5 µM), FGF1 (100 ng/ml), or CHIR+FGF1 (5 µM, 100 ng/ml, respectively) for 24 hours and subjected to Western blot analyses. These assays demonstrated the expression of various cell cycle regulatory proteins, such as cyclins, CDKs, c-Myc, GSK3, β-catenin, shown in Supplemental Figure 8C. Semi-quantitative Western blot analyses confirmed that the expression levels of cyclin D1, cyclin H, CDK4, c-Myc, β-catenin, were significantly upregulated in the CHIR+FGF1 treatment groups compared with the other treatment and control groups, shown in Supplemental Figure 8D. The expression levels of the remaining cyclins (A2, D2, E1, and E2), CDK7 and GSK-3α/β, were similarly expressed, shown in Supplemental Figure 8E. The expression of the receptors for FGF and VEGF indicated that FGF Receptor 1 (FGFR1) was significantly upregulated when treated with FGF1 or CHIR+FGF1 (Supplemental Figure 9A) while VEGF Receptor 2 (VEGFR2) was significantly upregulated by CHIR or CHIR+FGF1 compared with the other treatment groups (Supplemental Figure 9B).
Discussion

Mammalian cardiomyocytes lose their cell cycle soon after birth(12, 13). The loss of cardiomyocytes after a coronary occlusive ischemic injury is typically replaced by a fibrotic scar, which is often followed by post infarction LV remodeling that characterized by LV dilatation leading to heart failure. In the past a few decades, huge efforts have been invested in reactivating the cell cycle and regeneration capacity of cardiomyocytes in injured hearts. It has been shown that reactivation of cardiomyocyte cell cycle in genetically modified mouse models, regenerates the injured myocardium and improves LV function(14, 15). In the present study, we seek to identify small molecules or compounds to stimulate adult cardiomyocyte proliferation, and to prevent LV dilatation in hearts with post infarction LV remodeling. Using the hiPSC-CMs, the initial in vitro screening studies have revealed that a combination of CHIR+FGF1 enhances cardiomyocyte cell cycle. Interestingly, a combination of CHIR+FGF1 indeed confers cardioprotection when administered in the ischemic hearts, as evidenced by the improved cardiac function (Figure 1A-1E, Figure 5A-5G) and reduced size of fibrotic scar (Figure 1F-1G; Figure 5H-5J) in both mouse and pig models of myocardial infarction. However, in contrast to immature myocytes that derived from hiPSCs, these chemicals failed to stimulate cell cycle of mature cardiomyocytes in culture (Supplemental Figure 4) or endogenous cardiomyocytes in both mice and pigs (Figure 6D-6G). This discrepancy may be explained by the difference of cell cycle regulation network between humans and lower mammalian hearts, or by the differences of the immature nature of hiPSC-CMs vs the mature myocytes in vivo. One of these differences which could be relevant to our findings is the metabolic switch from glycolysis to oxidative phosphorylation, which seems to be a key driver for arresting cardiomyocyte proliferation(16). Nevertheless, the combination of CHIR+FGF1 robustly stimulates the angiogenesis in the LV of hearts in both mouse model (Figure 4A-4C) and pig model (Figure 7A-7G) of post infarction LV remodeling. Further studies revealed that the combination of CHIR+FGF1 promotes the cell cycle of ECs and SMCs in vitro (Supplemental Figure 5 and 6) and in vivo (Figure 4D-4G; Figure 7H-7J). In addition, the combination of CHIR+FGF1 protects cardiomyocytes from undergoing apoptosis in both mice (Figure 3A-3B) and pigs (Figure 6H-6K). Taken together, these data demonstrate for the first time that the combination of CHIR+FGF1 results in cardioprotection in vivo that is evidenced by a significant reduction of infarct size and the improved LV chamber function.

Previous studies have shown that FGF1-loaded PLGA microparticles resulted in enhanced recovery of LV function when administered into an infarcted myocardium(3). Similarly, CHIR-loaded NPs efficiently direct reprogramming of fibroblasts into functional cardiomyocytes and have been shown to be an attractive therapeutic option to replenish the lost cardiomyocytes(4). However, the synergetic therapeutic efficacy of the combined use of these two factors had not yet been explored. Wnt signaling pathways are expressed in multiple tissues and have pleiotropic effects on cell survival, proliferation, differentiation, migration, and apoptosis(17-19). In addition, the Wnt pathway plays an important role in angiogenesis and vascular remodeling(17, 18, 20), under normal and pathological conditions(21-23). CHIR is an inhibitor of GSK3, which has been shown effective in vitro for driving pluripotent stem cells towards the cardiac
mesoderm(24, 25), and promoting their proliferation. Furthermore, inhibition of GSK3β activity has also been shown to induce an apoptotic cascade in human transformed pancreatic epithelial cells, but not in non-transformed pancreatic cells by JNK (c-Jun N-terminal kinases) signaling pathway (26) thereby suggesting that the regulation of CHIR on apoptosis, whether positive or negative, may depend on both cell type and context (26, 27). In the present study, we used CHIR to activate pharmacologically the canonical Wnt pathway, which synergistically induced robust neo-angiogenesis around peri-infarct border zones, reduced the apoptotic rate of vascular cells and increased the proliferation rate of these cells during ischemia or reperfusion. The results are consistent with the gene expression profile of HUVEC as assessed by RNA sequencing (Supplemental Figure 7). FGF1, also known as acidic fibroblast growth factor (aFGF), is one of the prototype members of the heparin-binding FGF families (28) and is implicated in cardiogenesis through its synergizing action with bone morphogenetic proteins for inducing mesoderm-to-cardiac differentiation (24). FGF1 is multifunctional and features broad mitogenic and cell survival activities, including cell growth, morphogenesis, tissue repair, tumor growth and invasion. This protein functions as a modifier of endothelial proliferation and cell migration, as well as an angiogenic factor (29, 30). Nabel and co-workers have demonstrated that recombinant FGF-1 (rFGF-1) could promote intimal hyperplasia and angiogenesis in arteries in vivo (29) and FGF2/6 strongly promotes skeletal myocyte regeneration in conjunction with an increased neo-angiogenic response (31). Additionally, FGF1 has been shown to reduce apoptosis in vascular injury (11, 32-34). Studies using the native form of FGF1 delivered either by continuous release into the coronary artery or to the left atrium failed to demonstrate any beneficial effect (35-37). The growth factor did not increase the number of new collateral vessels within a few hours of injection. Thus, alternative mechanisms of FGF-induced reduction of infarct size, i.e., an increase in myocyte viability and resistance to injury (38), restoration of ischemia-impaired endothelium-dependent vasomotion (39), or recruitment of preexisting collaterals might explain this result (40). Many growth factors are capable of inducing physiologically significant angiogenesis in experimental animals. However, clinical trials such as the randomized evaluation of VEGF and the angiogenic gene therapy trial, did not produce encouraging results (41-43). It is noteworthy that virtually all clinical trials were carried out as a monotherapy. It is reasonable to hypothesize that administration of a combination of two or more growth factors may be superior to single agents (40, 44). In the present study, the combination of CHIR and FGF1 NPs that act on mechanistically distinct signaling pathways resulted in the best outcomes. Future directions may include testing the efficacy and optimize the dose of these growth factors in combination, which may further improve clinically relevant outcomes (44).

However, another factor that has so far hindered the efficacy of myocardial regenerating strategies is the low retention of biologics (cells or biomolecules) following their direct intramyocardial delivery. Indeed, it makes sense to hypothesize that a single shot of any of these biologics is unlikely to be therapeutically effective because of its expectedly fast clearance from the target tissue. To overcome this hurdle, the ability of HUVECs and HVSMCs to uptake PLGA NPs was leveraged to use this biomaterial as a slow-release vehicle intended to extend the exposure time of the myocardium to the particle-loaded agents. PLGA-based nanomaterials have been designed and deployed for the
treatment of MI(1, 2) and may promote revascularization of ischemic myocardium, by enabling the sustained release of a therapeutic cocktail of growth factors/cytokines/small molecules. Along with the nature of the delivered compounds, this delivery strategy may have contributed to the superior outcomes yielded by our combined treatment group.

**Study Limitations:** It is noteworthy that apoptosis has been reported to peak during the early postinfarction reperfusion period(45), which may have facilitated the demonstration of the efficacy of the two chemicals since they were delivered at the time of the acute injury. Whether similar improvements could be achieved by delaying the treatment to a more chronic phase remains to be determined. We used PLGA nanoparticles to delivery CHIR and FGF1, a testing of nanomaterials and their interaction with these two chemicals is necessary in order to optimize the release kinetics and thus, improve therapeutic effects. PLGA is a Food and Drug Administration-approved biomaterial which has been extensively used as a carrier of chemotherapeutic agents(46), and features a long-standing safety record in the clinics and current efforts at surface functionalization of NPs should further improve the efficiency of their payload delivery(47). On the other hand, in a translational perspective, the issues raised by biomaterials should not be underscored. Those include control of degradation kinetics through fine-tuning of their physico-chemical properties, assessment of possible inflammatory and immune responses, biodistribution patterns, ultimate fate of the materials once phagocytosed by the mononuclear phagocyte system scalability and manufacturing costs.
Methods

Generation and characterization of PLGA nanoparticles

PLGA nanoparticles (NPs) were prepared as described previously(2). A double-emulsion (water/oil/water phase) technique for recombinant human FGF1 acidic protein (rhFGF1, aa 16-155) and a single-emulsion (oil/water phase) for CHIR99021 were employed. FGF1 (water soluble) and CHIR (water insoluble) were loaded into separate nanoparticles, and their encapsulation efficiency and release kinetics were determined separately. The nanoparticles were mixed together before injection into animal hearts. Briefly, a solution of PLGA (100 mg) in dichloromethane (5 ml) with or without FGF1 (200 µl at 1 mg/ml), CHIR99021 (200 µl at 8 mg/ml), or coumarin-6 (1 mg), were sonicated at 4°C for 2 minutes (40% amplitude, pulse 40 seconds, pause 20 seconds). Next, for FGF1, 20 ml of a 4% (w/v) polyvinyl alcohol (PVA)-water solution was added, and for CHIR99021, 20 ml of a 1% (w/v) dimethylamine borane (DMAB)-water solution was added, and the mixtures were once again sonicated at 4°C for 2 minutes (40% amplitude, pulse 40 seconds, pause 20 seconds). The resultant mixture was transferred to 10 ml of a 4% (w/v) PVA-water solution and 20 ml of Milli-Q water for FGF1 or 30 ml of Milli-Q water for CHIR99021, in a 100 ml glass beaker and stirred for 4 hours until the dichloromethane was evaporated completely. Then, the solution was spun at 1000 g for 10 minutes to remove any aggregate, and the resultant supernatant was centrifuged again at 45000 g for 20 minutes to collect the NPs. The NPs were washed twice by resuspending them in 50 ml of Milli-Q water. Finally, the suspension was centrifuged at 45000 g for 20 minutes, frozen at -80°C overnight, lyophilized for 48 hours, and stored in -80°C until further use.

Measurement of the sizes PLGA NPs was performed using a Quanta scanning electron microscope (Quanta FEG 650, Hillsboro, OR). The quantification of particle diameter was performed using NIH ImageJ software. The release kinetics was determined by slide-a-lyzer mini dialysis devices, 20k MWCO, 0.5ml, with suspending the generated CHIR- or FGF1-NPs in the release medium, consisting of DPBS with 0.1% BSA and 0.02% sodium azide. The suspensions were incubated at 37°C under constant shaking, followed by withdrawing and replacing 14.5ml of the medium at the defined time points. To measure CHIR and FGF1 levels, the collected samples were analyzed using nanodrop via UV/Vis spec (for CHIR) or an enzyme-linked immunosorbent assay (ELISA) (for FGF1), respectively.

Characterization of cellular uptake and biodistribution of PLGA NPs

To characterize the cellular uptake of PLGA NPs, HUVECs and HVSMCs were seeded onto a Lab-Tek™ chamber slide system (Nunc™, Thermo Fisher Scientific) at a density of 1.5 x 10^4 cells/well and expanded with appropriate medium until 70% confluence. Next, the HUVECs/HVSMCs were synchronized by serum deprivation for 24 hours. Afterwards, the cells were treated with coumarin-6-loaded NPs (2 µg/ml) and incubated at 37°C with 5% CO₂ for 24 hours using appropriate complete medium. Finally, after 24 hours, the cells were washed twice with DPBS, pH 7.4 and were analyzed using a fluorescent microscope for cellular localization and distribution of NPs.

To further study if NPs were preferentially taken up by different cells, we mixed HUVECs, SMCs, hiPSC-CMs and fibroblasts with ratio of 1:1:1:1 and cultured them to
70% confluence. Then, the cells were treated with coumarin-6-loaded nanoparticles (2 µg/ml) and incubated at 37°C with 5% CO2 for 24 hours using appropriate complete medium. Finally, after 24 hours, the cells were washed twice with DPBS, pH 7.4 and were analyzed using a fluorescent microscope for cellular localization and distribution of nanoparticles.

**Mouse MI Model**

Surgical induction of MI was performed on 8- to 10-week old C57BL/6 mice (The Jackson Laboratory). In brief, mice were intubated and connected to ventilator while breathing 2% isoflurane USP (Fluriso™, VetOne) for maintenance of anesthesia. The heart was exposed through a left thoracotomy, and MI was induced by a permanent ligation of the left anterior descending coronary artery (LAD) with an 8-0 non-absorbable suture(48). NPs were resuspended in DPBS (pH 7.4), containing 0.1% bovine serum albumin (BSA)/0.02% sodium azide and the suspension was sonicated (40% amplitude, ~40-second intervals with 20-second pauses for a total of 2 minutes) on ice. A mixture of 15 µl of NPs loaded with CHIR+FGF1 (20 µg/µl, 13.33 µg/µl, respectively) was immediately delivered into the infarct (one) and border (two) zones by three intra-myocardial injections (equal volume, 5 µl/site), using a modified Hamilton needle to make the treatment dose of 2400 ng for CHIR (loading efficiency 1 mg CHIR-NPs = 8 µg CHIR) and 200 ng for FGF1 (loading efficiency 1 mg FGF1-NPs = 1 µg FGF1) (n=12). An equal volume of DPBS (n = 11) or non-loaded NPs (n = 11) was delivered in controls. In the sham group (n = 10), suture was passed around LAD without ligation. After chest closure, buprenorphine hydrochloride (0.1 mg/kg, Buprenex, Reckitt Benckiser Pharmaceuticals Inc.) and carprofen (5 mg/kg, Rimadyl, Zoetis) were given as intraperitoneal (IP) injections for every 12 hours, for 3 and 1 days post-surgery, respectively. Four animals died due to peri-/post-operative complications.

**Pig Ischemia-Reperfusion Injury Model**

Surgical induction of myocardial IR injury was performed on 45-day old female Yorkshire swine (14 kg, Snyder Farms, Birmingham), as described previously(49). Briefly, swine were intubated, and connected to ventilator while breathing 2% isoflurane USP (Fluriso™, VetOne) for maintenance of anesthesia. Throughout surgery, the animal body temperature, arterial blood pressure, ECG, and oxygen saturation were continuously monitored. A median sternotomy was performed, the LAD coronary artery distal to the second diagonal were identified and completely occluded for 60 minutes to generate AMI, followed by reperfusion. The NPs were administrated 15 minutes after reperfusion after systemic hemodynamics stabilized. A mixture of 1000 µl of resuspended NPs loaded with CHIR+FGF1 (20 µg/µl, 13.33 µg/µl, respectively) was delivered into the peri-infarct zones (equal volume, 200 µl/site x 5), using a modified Hamilton needle to make the treatment dose of 160 µg for CHIR (loading efficiency 1 mg CHIR-NPs = 8 µg CHIR) and 13.3 µg for FGF1 (loading efficiency 1 mg FGF1-NPs = 1 µg FGF1) (n = 4). An equal volume of DPBS (pH 7.4) was delivered in the untreated control group (n =4). Four size- and weight- matched animals served as additional controls. After chest closure, buprenorphine hydrochloride SR (0.24 mg/kg, Buprenex, Reckitt Benckiser Pharmaceuticals Inc.) was given as subcutaneous injections (SC) for every 72 hours, up to 3 days post-surgery; and
carprofen (4 mg/kg, Rimadyl, Zoetis) was injected intra-muscularly for every 24 hours, for 2 days post-surgery. Two animals were subjected to this IR and protocol (n = 10), died within first 24 hours after the LAD ligation. One of them died due to operative complications, and the another one due to perioperative uncontrolled cardiac arrhythmia.

**Echocardiography**

Pre- and post-MI (on day 28), the NPs-treated and control untreated mice were subjected to echocardiographic imaging as previously described(48). In brief, animals were maintained under 1.5 – 2% isoflurane USP (Fluriso, VetOne) anesthesia until the heart rate was stabilized at 400 to 500 bpm. The B-mode and two-dimensional M-mode images were acquired from both long-axis and short-axis views with a high-resolution micro-ultrasound system (Vevo 2100, VisualSonics, Inc.). Finally, the obtained data were analyzed and left ventricular (LV) EF, fractional shortening (FS), end-diastolic diameter (EDD), and end-systolic diameter (ESD) were calculated using Vevo analysis software. The operator was kept blinded to the experimental groups.

**Cardiac Magnetic Resonance Imaging**

Pre- and post-IR (on day 7 and day 28), the NPs-treated and control untreated pigs were subjected to cardiac magnetic resonance imaging (MRI) with a 1.5 Tesla clinical scanner (Siemens Sonta, Siemens Medical System) and a phased-array four-channel surface coil with ECG gating, as described previously(49, 50). Briefly, animals were anesthetized through inhalation of 2% isoflurane and placed in a supine position within the scanner. LV EF was calculated from a stack of short-axis cine images, using QMASS analytical software program (Medis Medical Imaging Systems, Leiden, The Netherlands). The cine imaging was performed with the following parameters: TR = 3.1 ms, TE = 1.6 ms, FA = 79°, matrix size = 256 x 120, FOV = 340 x 265 mm², and slice thickness = 6 mm (with a 4-mm gap between slices). Twenty-five phases were acquired across the cardiac cycle. Infarct characterization and quantification were measured by delayed enhancement (DE) cardiac MRI (Magnevist, Gadopentetate Dimeglumine: 0.20 mmol/kg, i.v. bolus) and the data are presented as the ratio of scar surface area to the total LV surface area. DE-MRI was performed with following parameters: TR = 16 ms, TE = 4 ms, FA = 30°, matrix size = 256 x 148, FOV = 320 x 185 mm², and slice thickness = 6 mm (with a 0-mm gap between slices). [TR, time to repetition; TE, time to echo; FA, flip angle, FOV, field of view].

**Determination of infarct size**

Following the coronary occlusion, at day 28 post-MI, under deep anesthesia, the hearts were excised from groups of 6 mice, and the infarct size was evaluated as described previously(51, 52). Briefly, the excised hearts were fixed in 10% phosphate-buffered formalin for 24 hours. Next, the hearts were embedded in optical cutting temperature (O.C.T) compound for cryopreservation. Ten-micron-thick coronal sections of the entire ventricles were cut from base to apex and mounted on glass slides. Next, every 30th section was fixed in Bouin’s solution and stained with 0.04% Sirius Red / 0.1% Fast Green collagen staining.
In a similar fashion, the LV walls of the pigs were cut transversely into five short axis slices (R1 to R5) from base to apex. Each slice was sequentially cut into eight samples (S1 to S8) according to coronary perfusion physiology, and the S1 of R2 (i.e., the site of anterior wall for NPs application) was collected and processed for cryosectioning and stained with Sirius Red and Fast Green.

To assess the quantitative changes in infarct size at Day 28 post AMI, digital images of the stained sections were captured using an Olympus light microscopy. Morphometric analyses were carried out using NIH ImageJ software. The size of the infarct was calculated according to the following formula: Infarct size % = [Sum of (scar circumferential length X thickness of each of the short axis) / Sum of (short axis left ventricle length X thickness of the short axis)] X 100%.

Quantification of Angiogenesis

The angiogenic response in the border zone of infarcted myocardium, i.e., vessel density (capillary/arterial), was evaluated by immunostaining and fluorescence microscopy. Briefly, at 28 days posttreatment (MI or IR), cardiac tissue sections were sequentially stained with cardiac, endothelial and smooth muscle cells markers, i.e., cTnT, isolectin B4 (Griffonia Simplicifolia Lectin I, GSL I), and SM22α, respectively, and nuclei were counterstained with DAPI(53). We used NE-Cadherin positive counts/MM² for all vessel density, and SMC22α positive counts/MM² for arteriolar density.

Screening of Chemicals that Enhances Cardiomyocyte Cell Cycle

Using 5-Bromo-2′-deoxy-uridine (BrdU) incorporation assay, we screened several different chemicals that were reported to be able to enhance cell cycle activity of cultured cardiomyocytes derived from human induced pluripotent stem cells (hiPSCs), including Ly294002 (PI3 kinase inhibitor)(1), fibroblast growth factor 1 (FGF1)(1, 2), SB203580 and VX702 (p38 MAPK inhibitors)(1), KN93 (Ca2+/calmodulin-dependent protein kinase II inhibitor)(3), Su1498 (Flk-1 inhibitor)(3), and CHIR99021 (Wnt activator and GSK3α and 3ß inhibitor)(3, 4). The maintenance culture of hiPSCs and cardiomyocyte differentiation have been described before(5). In brief, 4 weeks after initiation of cardiomyocyte differentiation, individual chemicals or in combination were used to treat the cells for 24 hours. BrdU (15 µM final concentration) was added to the culture medium 12 hours prior to cell harvesting. The cells were fixed with ethanol at –20°C for 15 minutes, and BrdU staining was performed with a BrdU Labeling and Detection Kit (Roche life science, Inc. Cat # 11296736001) as directed by the manufacturer’s instructions. The cells were counter-stained for the expression of hcTnT and human Nkx2.5 to confirm hiPSC-CM identity. The number of nuclei that stained positively were counted, normalized to the total number of hiPSC-CMs (i.e., the number of hcTnT/Nkx2.5 double-positive cells), and expressed as a percentage. Each experiment was repeated 3-4 times.

HUVEC Culture: Expansion and Maintenance

Human umbilical vein endothelial cells (HUVECs) were purchased from ATCC (Manassas, VA. Cat: PCS-100-010) and were expanded and subcultured according to the manufacturer’s recommendations. Briefly, cells were thawed, seeded onto a fibronectin-precoated T75 flask (1µg/cm² or 0.5 µg/mL) and expanded using a complete
endothelial cell growth medium supplemented with 5% fetal bovine serum (FBS),
human fibroblast growth factor (hFGF), human epidermal growth factor (hEGF),
vascular endothelial growth factor (VEGF), R3-insulin-like growth factor-1 (RE3-IGF-1),
hydrocortisone, ascorbic acid, gentamicin, and amphotericin-B (GA1000) (Clonetics™,
EGM™-2MV BulletKit™; Lonza).

HVSMC Culture: Expansion and Maintenance

Human vascular smooth muscle cells (HVSMCs, primary pulmonary artery) were
procured from ATCC (Manassas, VA. Cat: PCS-100-023) and were expanded and
maintained as per the manufacturer’s instructions. Briefly, cells were thawed, plated
onto a T75 flask and expanded using a complete medium 231 (Thermo Fisher
Scientific) supplemented with 5% FBS (4.9% v/v), hbFGF (2 ng/ml), hEGF (0.5 ng/ml),
heparin (5ng/ml), recombinant human IGF-1 (2 µg/ml), and bovine serum albumin (BSA,
0.2 µg/ml) (SMGS, Thermo Fisher Scientific).

NCMs Culture: Isolation and Maintenance

Isolation of neonatal cardiac myocytes (NCMs) was performed as described in detail
previously(6). Briefly, under deep euthanasia, 1-day old C57BL/6 neonatal mice (The
Jackson Laboratory) were subjected to cervical dislocation and hearts were dissected
out from these mice and pooled in ice-cold DPBS, pH 7.4, containing 2mM 2,3-
butanediol monoxime (BDM), and rinsed three times. Next, the hearts were minced
thoroughly and incubated with 10 ml of isolation medium (20 mM BDM and 0.0125%
trypsin in Dulbecco’s phosphate-buffered saline (DPBS, pH7.4) in a 4°C shaking water
bath overnight. The tissue fragments were pelleted at 800 g for 8 minutes, the
supernatant was discarded, and the obtained pellet was resuspended in 5 ml of
digestion medium (1.5 mg/ml collagenase and 20 mM BDM in Dulbecco’s Modified
Eagle’s Medium (DMEM) and oxygenated for 1 minute, then incubated at 37°C in a
shaking water bath for 20 to 30 minutes. Tissues were dissociated by repeated
triturations (at 8-minute intervals). The cells were once again pelleted and resuspended
in complete myogenic medium composed of DMEM (4.5 g/L glucose, L-glutamine, and
sodium pyruvate; Cellgro by Mediatech, Inc.) supplemented with 8% horse serum (HS,
lot-selected, Glbco), 5% newborn calf serum (NCS, Atlanta Biologicals, Inc.), penicillin
(100 U/ml), streptomycin (100 µg/ml), and amphotericin B (1 µg.ml). Furthermore, to
remove the co-existing cardiac fibroblasts and endothelial cells, the above cell
suspensions were plated in 100 mm2 cell culture dishes and incubated in a humidified
atmosphere of 5% CO2 at 37°C for 30 minutes. Following incubation, the non-adherent
myocytes were slightly tapped and were aspirated off immediately from the panning
dishes, and the procedure was repeated two more times. After panning, the cells were
once again pelleted and resuspended in myocyte medium. Finally, the isolated NCMs
were quantified using a hemocytometer and plated at a density of approximately 1.5 x
105 cells/cm2 onto cell culture dishes precoated with a monolayer of collagen. Cells
were seeded into the wells of a 6-well plate, incubated in a humidified atmosphere of
5% CO2 at 37°C for 48 hours, and observed under microscope for spontaneous beating
and rhythmicity. These NCMs were cultured in complete myocyte medium for an
additional 3 days.

Isolation and culture of cardiac Fibroblasts
Cardiac fibroblasts were isolated from porcine heart tissue at postnatal day 3 porcine. The tissue was washed twice in DPBS containing antibiotics in sterile condition and was then cut into small pieces, digested in 10ml 0.25% trypsin for 45 min incubation at 37°C in 10 cm dishes. Then the suspension was neutralized with 10 mL of complete culture medium (Dulbecco's modified Eagle's medium (DMEM, Sigma) supplemented with 10% FBS, 0.1 mM Non-Essential Amino Acid, 1 mM L-Glutamine, 0.1 mM 2-mercaptoethanol, 100 U/mL penicillin, 100 µg/mL streptomycin), passed through a 40 µm cell strainer and pelleted by centrifugation. The pellet was resuspended in 10 mL of complete culture medium. Then the cells were cultured in 10 cm dishes and allowed to adhere for 3 hours. Adherent cells were then gently washed once with pre-warmed DPBS supplemented with antibiotics, and the growth medium was replaced. Once reached 40–50% confluency, cells were passaged to a gelatin-precoated T75 flask and incubated in humidified 95% air with 5% CO2 at 37°C. Medium was changed every 2-3 days.

HUVECs, HVSMCs, NCMs and Fibroblasts: Cell Cycle Synchronization
The cell cycle synchronization of HUVECs, HVSMCs, NCMs and Fibroblasts cultures was performed by serum deprivation. In brief, cells were plated onto a T75 flask and expanded to 70 to 80%, using appropriate culture media. Then, the cells were rinsed twice with DPBS (pH 7.4) and incubated with appropriate serum-free culture medium for 24 hours. After 24 hours, they were exposed to CHIR, FGF1, or CHIR+FGF1 for 24 hours and cultured in appropriate complete medium. Finally, the cultures were terminated, and the collected samples were subjected to immunofluorescent staining for cell cycle markers and/or TUNEL assay; for HUVEC, next generation RNA sequencing (RNA-seq) was also performed. The data have been deposited in NCBI Gene Expression Omnibus (GEO) database and the accession number is GSE138837.

BrdU (5-bromo-2’-deoxy-uridine) labeling and detection by immunofluorescence
In brief, cell cycle synchronized HUVEC or HVSMC cultures that were treated with CHIR, FGF1, or CHIR+FGF1, were incubated with the S-phase marker, BrdU (10 µmol), in a humidified atmosphere of 5% CO2 at 37°C for 12 hours. Then, the cells were fixed with ice-cold 70% ethanol, pH 2.0 (50 mM glycine) for 15 minutes, and BrdU staining was performed using a BrdU Labeling and Detection Kit (Roche) according to the manufacturer’s instruction.

Immunostaining and Fluorescence Microscopy
The explanted hearts were collected at day 28 and processed according to previously described protocols(7). In brief, hearts were fixed in ice-cold 4% paraformaldehyde (PFA) for 4 hours followed by overnight immersion in 30% sucrose, at 4°C. Ten-µm serial cryosections were generated, and every 30th section was permeabilized with 0.2% Triton X-100, for 10 minutes at room temperature. Next, sections were blocked in 5% donkey serum in DPBS, pH 7.4 for 30 minutes at room temperature. The primary antibodies used are shown in Supplemental Table 2. Primary antibodies were used at 1:10 to 1:10000 dilutions in blocking buffer (1.5% BSA, 100 mM glycine in PBS) for 12 to 16 hours at 4°C. Secondary antibodies (FITC, CY™3, and CY™5 obtained from Jackson ImmunoResearch Laboratory) were used at 1:200 dilutions in blocking buffer for 2 hours at room temperature in the dark. Nuclei were stained with 4,6-diamidino-2-
phenyl-indole (DAPI, 100 ng/ml; Sigma-Aldrich). Negative controls for staining included only secondary antibodies. Finally, the sections were analyzed using a fluorescence microscope (Olympus IX81). Similarly, immunostaining was performed on ethanol-fixed cells, i.e., HUVECs, HVSMCs, or NCMs for various phenotypic as well as cell cycle markers.

**Detection of Apoptotic Cells by TUNEL Assay**

The in situ cell death detection kit (ApopTag Fluorescein, Chemicon) was used for the detection and quantification of apoptosis at the single-cell level using a fluorescence microscope. Briefly, samples (cryotissue sections) were collected at defined time points, rinsed twice in DPBS, pH 7.4, and fixed in 4% PFA at room temperature for 20 minutes. The labeling reactions with the TUNEL reaction mixture were carried out as per the manufacturer’s instructions. Finally, the samples were mounted in Vectashield mounting medium with DAPI (Vector Laboratories). A minimum of 8 tissue sections from various zones (ischemic, border, remote) from each heart were evaluated.

**Reverse Transcription-Quantitative Real-Time Polymerase Chain Reaction (RT-qPCR)**

Total cellular RNA was extracted with Trizol™ reagent (Thermo Fisher Scientific) and treated with DNasel to remove genomic DNA (gDNA) contaminants. The RT reaction was executed using 500 ng of total RNA in a final reaction volume of 20 µl using a SuperScript IV First-Strand Synthesis System (Invitrogen) according to the manufacturer’s protocols. The cyclin D1 (CCND1), cyclin D2 (CCND2), cyclin dependent kinase 1 (CDK1), cyclin dependent kinase 4 (CDK4), catenin beta 1 (CTNNB1), MYC proto-oncogene, BHLH transcription factor (c-Myc), and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) primers were designed using a web-based software, synthesized commercially (Thermo Fisher Scientific), and evaluated for a range of annealing temperature, 58°C to 61°C, for all the primer pairs, as shown in Supplemental Table 1.

All RT-qPCRs were carried out using Fast SYBR Green Master Mix (Thermo Fisher Scientific) in a QuantStudio™ 3 Real-Time PCR System (Applied Biosystems) and CT (threshold cycle) values were computed using QuantStudio™ Design and Analysis Software (v1.4.3). The PCR protocol was performed with the primer sequences listed in Supplemental Table 1, and consisted of 40 cycles of denaturation at 94°C for 15 seconds, annealing at 60°C for 15 seconds, and extension at 72°C for 1 minute, followed by a single 7-minute extension period at 72°C. Measurements were normalized to the level of endogenous GAPDH.

**Western Blotting**

Lysis and extraction of total cellular proteins were carried out using M-PER mammalian protein extraction reagent (Thermo Fisher Scientific), consisting of a cocktail of protease- and phosphatase-inhibitors (Thermo Fisher Scientific), as per the manufacturer’s instructions. Next, the isolated proteins were quantified using either a Pierce™ Coomassie plus (Bradford) or a bicinechonic acid (BCA) protein assay kit. Proteins were separated by 4% to 20% sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE, Precast Gels, Bio-Rad), and electroblotted onto a
polyvinylidene difluoride (PVDF) membrane (Trans-Blot® Turbo™ Mini PVDF Transfer Packs, Bio-Rad). Then, the membranes were blocked with 5% BSA, subjected to immunostaining with appropriate dilutions of primary antibodies as shown in Supplemental Table 2 and detected using horseradish peroxidase (HRP)-conjugated secondary antibodies. Western blot signals were measured by densitometry and were analyzed using a software (AlphaView SA software 3.4, ProteinSimple). The housekeeping protein, GAPDH, was used for Western blot normalization.

**Optimization of the concentration of CHIR and FGF1**

To determine the optimal concentration of CHIR and FGF1 on the activation, proliferation and cell cycle progression of HUVECs, the cell cycle synchronized in vitro HUVEC cultures were treated with various concentrations of CHIR (0.5 µM, 5 µM, or 50 µM) or FGF1 (10 ng/ml, 100 ng/ml, or 1000 ng/ml) for 24 hours and assessed by immunostaining and fluorescent microscopic analyses for BrdU (S phase marker) incorporation patterns (Supplemental Figure 10A-10B). Quantification of the percentage of CD31-positive (red, CD31) HUVECs showed that the incorporation of BrdU were significantly higher in the 5 µM CHIR-treated group than in the 0.5 µM CHIR-treated or control groups (Supplemental Figure 10C). Interestingly, HUVECs treated with a higher concentration of CHIR (50 µM) underwent a significant amount of cellular senescence and death, resulting in complete detachment and floating of cells within 24 hours of treatment (data not shown). Similarly, quantification of the percentage of CD31-positive HUVECs revealed that the incorporation of BrdU were significantly greater in the 100 ng/ml FGF1-treated group compared with other treatment (10 ng/ml or 1000 ng/ml) and control groups (Supplemental Figure 10D).

**Antibodies**

The following primary antibodies were used in the study: Mouse anti-cardiac troponin T monoclonal antibody (1:100, Abcam, catalog ab10214); mouse anti-sarcomeric alpha actinin monoclonal antibody (1:100, Abcam, catalog ab9465); goat anti-cardiac troponin I polyclonal antibody (1:100, Abcam, catalog ab188877); mouse anti- Myosin 4 monoclonal antibody (1:100, Invitrogen, catalog 50-6503-82); wheat germ agglutinin (1:1000, Thermo Fisher, catalog W11261); mouse anti-CD31 monoclonal antibody (1:100, Abcam, catalog ab9498); rabbit anti-CD31 polyclonal antibody (1:100, Abcam, catalog ab28364); goat anti-CD31 polyclonal antibody (1:100, R&D, catalog AF3628); rabbit anti-vimentin monoclonal antibody (1:100, Abcam, catalog ab92547); fluorescein labeled griffonia simplicifolia lectin I (GSL I) isolectin B4 (1:10, vector laboratories, catalog FL-1201); rabbit anti-SM22 alpha polyclonal antibody (1:100, Abcam, catalog ab14106); rabbit anti-Cyclin D1 monoclonal antibody (1:1000, Abcam, catalog ab134175); rabbit anti-Cyclin D2 polyclonal antibody (1:500, Santa Cruz, catalog sc-593); Cyclin Antibody Sampler Kit (Cyclin A2, E1, E2, H, CDK4, CDK7) (1:1000, Cell Signaling Technology, catalog 9869T); rabbit anti-c-Myc monoclonal antibody (1:10000, Abcam, catalog ab32072); mouse anti-Histone H3 (phospho S10) monoclonal antibody (1:100, Abcam, catalog ab14955); rabbit anti-phospho-Histone H3 (Ser10) polyclonal antibody (1:200, Millipore-Sigma, catalog 06-570); rabbit anti-Ki-67 polyclonal antibody (1:100, Millipore-Sigma, catalog AB9260); mouse anti-Ki-67 clone Ki-S5 monoclonal antibody (1:100, Millipore-Sigma, catalog MAB4190); mouse anti- Aurora B monoclonal antibody (1:100, Abcam, catalog ab3609); rabbit anti-GSK3 beta + GSK3 alpha
monoclonal antibody (1:1000, Abcam, catalog ab185141); rabbit anti-GSK3 (alpha + beta) (phospho Y216 + Y279) monoclonal antibody (1:1000, Abcam, catalog ab68476); rabbit anti-beta Catenin monoclonal antibody (1:1000, Abcam, catalog ab6302); rabbit anti-FGFR1 polyclonal antibody (1:1000, Abcam, catalog ab10646); rabbit anti-VEGF Receptor 1 + VEGF Receptor 2 polyclonal antibody (1:1000, Abcam, catalog ab36844).

**Statistics**
All the data are presented as mean ± standard error of the mean (mean ± SE). For all the experimental data, the differences among the groups were determined by applying ANOVA (comparison among more than two groups) and adjustment for multiple comparisons by Dunn’s multiple comparisons test; and by applying unpaired Student’s t-test (2 tailed) when comparison between two groups. A $p$ value < 0.05 was considered statistically significant.

**Study approval**
All experimental protocols were approved by The Institutional Animal Care and Use Committee (IACUC) of the University of Alabama at Birmingham and performed in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals (NIH publication No 85-23).
Author contributions
C.F., W.Z., J.Y. and J.Z. conceived and designed the project. Y.O. designed and developed the nanoparticle formulations, Y.O. and D.P. generated the nanoparticles. M.Z. and W.Z. performed chemical screening on hiPSCs. C.F., X.L. and Y.T. performed histology, western blot, and RT-PCR to test the effects on nanoparticles on hiPSC-CMs, HUVECs, SMCs and fibroblasts. C.F. performed mouse surgery, echocardiography, tissue collection and characterization. G.P.W. performed pig surgery and nanoparticle injection. C.F., Y.T. and G.P.W. performed pig MRI. C.F. collected pig tissue and performed histology of these tissue samples. C.F., X.L., D.P., W.Z., and J.Z. performed data analysis and statistical analysis. C.F., M.T.V., P.K., P.M., W.Z., and J.Z. prepared the manuscript.
Acknowledgments

We would also like to thank Dr. Mary Flowers Braswell for her generous donation of the “Echocardiographic Imaging System,” for research purposes. This work was supported by National Institute of Health grants (NHLBI R01 grants: HL095077, HL114120, HL131017, HL142627; and U01 HL134764); by an award from the American Heart Association-National Scientist Development grant (16SDG30410018).

Figures and figure legends

Figure 1. CHIR99021 and/or FGF1 nanoparticles (NPs) treatment: assessment of cardiac function and infarct size in a mouse model of myocardial infarction (MI). Mice that were treated with intramyocardial injections of different NPs including, CHIR+FGF1-NPs, CHIR-NPs, FGF1-NPs, and empty NPs (non-loaded), a MI only control mice, and sham-operated control mice were subjected to echocardiographic assessments of left ventricular (LV) function (A). Ejection fraction (EF) (B), fractional shortening (FS) (C), end systolic diameter of LV (D), and end diastolic diameter of LV (E) were assessed before MI induction (pre-S) and on post-MI day 28 (post-S). On day 28 post MI, CHIR+FGF1-NPs treatment groups presented significantly greater EF and FS compared with other treatment as well as control groups (B, C) and significantly lower values of systolic-/diastolic-diameters of the LV. Data are given as means ± SE.10-12 animals per group. (Statistical analysis: Two-way ANOVA with Dunn's multiple comparisons test. *p < 0.01 vs. sham; †p < 0.01 vs. MI; ‡p < 0.05 vs. empty NPs; §p < 0.05 vs. CHIR-NPs, ||p < 0.01 vs. FGF1-NPs.) Sirius Red/Fast Green histochemical staining revealing areas of infarcted (red, non-viable) and non-infarcted (green, viable) zones in post MI day 28 ventricular tissue sections (F). The infarct size was quantified.
as the ratio of the scar area to the total surface area of the left ventricle and expressed as a percentage, for day 28 samples (G). At day 28, the CHIR+FGF1-NPs treatment group showed significant reduction in infarct size compared with other NPs treatment groups or the untreated control MI animals. Scale bar = 1000 µm (Panels in F). Data are given as means ± SE. 10-12 animals per group. Statistical analysis: One-way ANOVA with Dunn’s multiple comparisons test. *p < 0.01 vs. MI; †p < 0.01 vs. Empty NP; ‡p < 0.01 vs. CHIR-NP; §p < 0.01 vs. FGF1-NP.

Figure 2. Direct intramyocardial injection of free CHIR99021 and/or FGF1: assessment of cardiac function and infarct size in a mouse model of myocardial infarction (MI). Mice were treated with direct intramyocardial injections of free CHIR, FGF1, and CHIR+FGF1 while MI-only served as controls. (A) Echocardiographic assessment of LV function. EF (B) and FS (C) were determined before MI (pre-S) and after 28 days (post-S). On day 28 post MI, no difference was identified among different treatment groups (means ± SE, 5 animals per group). (D) Fibrosis, as assessed by Sirius Red/Fast Green histochemical staining (scale bar = 1000 µm). At day 28, fibrosis, expressed as the ratio of the scar area to the total surface area of the LV, did not differ between groups (E). 5 animals per group. Statistical analysis: Two-way
ANOVA (B and C) and one-way ANOVA (E) with Dunn’s multiple comparisons test. *p < 0.01 vs. sham.

Figure 3. Detection and quantification of apoptosis by TUNEL assay in the mouse model of myocardial infarction (MI). (A) Seventy-two hours post-treatment, the CHIR+FGF1-NPs treatment group showed significantly fewer numbers of TUNEL-positive cells in the border zone compared with the other treatment groups (scale bar = 50 µm) (B). Cells were also counterstained for nuclei (blue, DAPI). Data are given as means ± SE. 5 animals per group. Statistical analysis: One-way ANOVA with Dunn’s multiple comparisons test. *p < 0.01 vs. sham; †p < 0.01 vs. MI; ‡p < 0.01 vs. empty NP; §p < 0.01 vs. CHIR-NPs; ||p < 0.01 vs. FGF1-NPs.
Figure 4. Evaluation of nanoparticle- (NPs) mediated neo-angiogenesis in the mouse model of myocardial infarction (MI). (A) Expression of the endothelial specific lectin, isolectin B4 (red, IB4) and smooth muscle protein, SM22-alpha (green, SM22α) in the peri-infarct border zone sections 28 days post MI (scale bar = 50 µm). (B and C) Graphical expression of angiogenesis data. The CHIR+FGF1-NPs-treated group showed significantly elevated vascular densities compared with other NPs treatment groups and the untreated MI group, but no significant difference in vascular densities was observed between CHIR+FGF1-NPs treatment and the sham-operated controls. Data are given as means ± SE.10-12 animals per group. Statistical analysis: One-way ANOVA with Dunn's multiple comparisons test. *p < 0.01 vs. sham; †p < 0.01 vs. MI; ‡p < 0.01 vs. empty NPs; §p < 0.01 vs. CHIR-NPs; ||p < 0.01 vs. FGF1-NPs). (D-G) Cell cycle activity of endothelial cells assessed by a dual staining for Ki-67 (green) and isolectin B4 (red; D, F) and PH3 (green) and isolectin B4 (red; E, G). Scale bar = 20 µm. Data are given as means ± SE.10-12 animals per group. Statistical analysis: One-way ANOVA with Dunn's multiple comparisons test. *p < 0.01 vs. sham; †p < 0.01 vs. MI; ‡p < 0.01 vs. empty NPs; §p < 0.01 vs. CHIR-NPs; ||p < 0.01 vs. FGF1-NPs.
Figure 5. Assessment of left ventricular (LV) morphology and function in a pig model of ischemia-reperfusion (IR) injury. Cardiac magnetic resonance imaging (MRI) recordings in the experimental groups at end-diastole (ED) and end-systole (ES). At day 28, CHIR+FGF1-NPs-treated group revealed significant reduction in infarct size compared with untreated IR group (B). On the contrary, EF (C), CO (D), and SV (E) were significantly greater in CHIR+FGF1-NPs-treated groups than in untreated IR groups while LVEDV and LVESV were significantly lower (F, G). Data are given as means ± SE. 4 animals per group. Statistical analysis: Two-way ANOVA with Dunn's multiple comparisons test. *p < 0.01 vs. pre-IR; †p < 0.05 vs. week1; ‡p < 0.05 vs. IR.

Macroscopic areas of infarction/fibrosis/scar (H) at Post IR day 28 inserial transverse sections of fresh (scale bar = 1 cm), representative micrographs of Sirius Red/Fast Green histochemical staining, revealing areas of infarcted (red, non-viable) and non-infarcted (green, viable) zones (I) (scale bar = 1 mm) and quantification of left anterior wall thickness (J). Data are given as means ± SE. 4 animals per group. Statistical analysis: One-way ANOVA with Dunn's multiple comparisons test. *p < 0.01 vs. Control; †p < 0.05 vs. IR.
Figure 6. Morphometric analysis of left ventricular (LV) hypertrophy, cardiomyocyte cell cycle and apoptosis in a pig model of ischemia-reperfusion (IR) injury. (A) Expression of a cardiac contractile protein, α-sarcomeric actinin (red, α-SA) and a plasma membrane marker, wheat germ agglutinin (green, WGA) in the peri-infarct border zone sections 28 days post MI (scale bar = 50µm).  (B and C) Markers of cardiomyocyte and LV hypertrophy showing a reduction in the treated group.  (D-G) Cardiomyocyte cell cycle activity assessed by dual stainings for Ki67 and cTnT (D and F) and for PH3 and cTnT (E and G). Data are given as means ± SE. 4 animals per group.  (H-K) Apoptosis in the infarct, border and remote zones (IZ, BZ and RZ, respectively), assessed by staining for TUNEL (red) and the pig cardiac specific contractile protein, sarcomeric alpha actinin (green, α-SA) (scale bar = 50 µm). The number of apoptotic cells did not differ between the control and treated groups in the RZ (K) but was significantly reduced in the treatment group in the IZ and BZ (I and J). Data are given as means ± SE. 4 animals per group. Statistical analysis: One-way ANOVA with Dunn’s multiple comparisons test (B, C and I-K) and t test (F and G). *p < 0.05 vs. Control; †p < 0.05 vs. IR (B and C); *p < 0.01 vs. control; †p < 0.05 vs. IR (I-K).
Figure 7. Evaluation of nanoparticle- (NPs) mediated neo-angiogenesis in the pig model of ischemia-reperfusion (IR) injury. (A) Expression of cardiac specific regulatory protein, troponin T (white, cTnT), smooth muscle protein, SM22-alpha (green, SM22α), and endothelial specific lectin, isoelectin B4 (red, IB4) in the infarct, border and remote zones (IZ, BZ and RZ, respectively) 28 days post MI (scale bar=20um). (B-G) Vasculogenic responses showing that the two-factor-loaded nanomaterials increased angiogenesis compared with I/R untreated hearts in the infarct (B and C) and border (D and E) zones but not in the remote one (F and G). Data are given as means ± SE. 4 animals per group. (H-J) Proliferation of cardiac microvascular endothelial cells assessed by dual staining for IB-4-positive cells and both Ki-67 (H and I) and PH3 (H and J) (scale bar = 50 µm). The results suggest that CHIR+FGF1-NPs synergistically promoted pig cardiac microvascular endothelial cell cycle activation and progression. Data are given as means ± SE. 4 animals per group. Statistical analysis: One-way ANOVA with Dunn’s multiple comparisons test. *p < 0.01 vs. control; †p < 0.05 vs. IR (B-G); *p< 0.05 vs. control; †p < 0.01 vs. IR (I and J).
