Abstract

Recovery from measles results in life-long protective immunity. To understand induction of long-term immunity, rhesus macaques were studied for six months after infection with WT measles virus (MeV). Infection caused viremia and rash with clearance of infectious virus by 14 days. MeV RNA persisted in PBMCs for 30-90 days and in lymphoid tissue for 6 months most often in B cells but was rarely detected in BM. Antibody with neutralizing activity and binding specificity for MeV nucleocapsid (N), hemagglutinin (H) and fusion proteins appeared with the rash and avidity matured over 3-4 months. Lymph nodes had increasing numbers of MeV-specific antibody-secreting cells (ASCs) and germinal centers with late hyalinization. ASCs appeared in circulation with the rash and continued to appear along with peripheral Tfh cells for the study duration. ASCs in lymph nodes and PBMCs produced antibody to both H and N, with more H-specific ASCs in BM. From 14-21 days 20-100-fold more total ASCs than MeV-specific ASCs appeared in circulation suggesting mobilization of pre-existing ASCs. Therefore, persistence of MeV RNA in lymphoid tissue was accompanied by continued germinal center formation, ASC production, avidity maturation and accumulation of H-specific ASCs in BM to sustain neutralizing antibody and protective immunity.
Despite the availability of safe and highly effective live attenuated measles virus (MeV) vaccines, measles continues to be a significant, and recently increasing, cause of morbidity and mortality with more than 100,000 deaths each year (1, 2). MeV is a highly infectious, negative-strand RNA virus transmitted by aerosol or respiratory droplets that causes a systemic rash disease in both humans and nonhuman primates (3, 4). MeV replicates in multiple types of cells including lymphocytes, monocytes, epithelial cells and endothelial cells (5, 6), with efficient transmission to susceptible individuals for several days before and after the onset of the rash (7). The rash appears 10-14 days after infection and coincides with the appearance of the adaptive immune response, clearance of infectious virus and clinical recovery (8). Despite the elimination of infectious virus, MeV RNA persists in peripheral blood mononuclear cells (PBMCs), urine and nasopharyngeal secretions of children with measles for at least 3-4 months (9, 10).

Detailed studies of rhesus macaques experimentally infected with WT MeV demonstrated that clearance of viral RNA from PBMCs occurs in three phases (8, 11). After an initial peak at 7-10 days, there is a rapid decline coincident with the clearance of infectious virus (10-14 days) followed by up to a 10-fold rebound (14-24 days) and then a slow decline to undetectable levels 30-90 days after infection. After clearance from PBMCs viral RNA is still detected in lymphoid tissues (8).

The host immune response to MeV is essential for viral clearance, clinical recovery and the establishment of life-long immunity (12). Measles is accompanied by a robust immune response and in general, the cellular immune response is most important for clearance while the humoral immune response is most important for protection against re-infection (13-16). MeV-specific IgM is detected after rash onset, is maintained for approximately 28 days (17, 18), and serves as a marker of primary infection. MeV-specific IgG responses appear 2-3 weeks after infection,
increase in amount and avidity over time (19), and are maintained for life (20), but the
techniques for establishing life-long protective immunity have not been defined.

MeV has six structural proteins: the hemagglutinin (H) and fusion (F) surface glycoproteins,
the matrix (M) protein, the nucleocapsid (N) protein, phosphoprotein (P) and large polymerase
protein (L). The most rapidly produced antibodies are against the MeV N protein, and the
absence of N-specific antibodies is used as an indicator of measles seronegativity (21, 22).
Antibodies to the H and F surface glycoproteins are important for virus neutralization and
protection from infection (23, 24).

Unlike infection with WT MeV, protective immunity induced by the live attenuated MeV
vaccine may not be life-long and waning immunity with secondary vaccine failure can occur (25-
28). Understanding the mechanisms involved in the generation and maintenance of life-long
protective immunity to measles is thus critical to assessing the challenges of achieving and
sustaining measles elimination through vaccination (29). To that end, we have characterized the
cell type-specific sites of viral RNA persistence and evolution of the MeV-specific antibody
response in rhesus macaques over six months after WT MeV infection. We have identified
ongoing changes in lymphoid tissue architecture, T follicular helper (Tfh) cells in circulation, and
the frequencies of MeV-specific antibody-secreting cells (ASCs) in lymphoid tissue, PBMCs and
BM associated with persistence of MeV RNA. These studies suggest that persistent viral RNA
and protein within lymphoid tissue promotes prolonged maturation and maintenance of the
MeV-specific neutralizing antibody response and life-long protective immunity.
RESULTS

MeV RNA persistence in immune cells

A total of 13 juvenile male rhesus macaques were infected intra-tracheally with WT MeV in three groups (cohort X=3, Y=5, U/V=5). PBMCs were assessed for infectious virus by co-cultivation on Vero/hSLAM cells and MeV RNA by qRT-PCR for the MeV N gene. All macaques developed a viremia 7-10 days after infection and a rash that appeared at 10-11 days. Infectious virus was cleared by 14 days with persistent MeV RNA in PBMCs that gradually decreased to undetectable levels 30 to 90 days after infection (Figure 1) (8, 11).

To determine whether CD3+ T cells were the primary sites of MeV RNA persistence in PBMCs, levels of RNA in isolated CD3+ T cells were compared to levels in the total PBMC population by qRT-PCR for the MeV N gene (Figure 2A). CD3+ T cells accounted for only a small proportion of the MeV RNA present in PBMCs. To further identify the cell types in which MeV RNA persists after clearance of infectious virus, PBMCs (Figure 2B) and inguinal lymph node mononuclear cells (Figure 2C) were sorted with magnetic beads into B cell, T cell, and monocyte populations and ddRT-PCR (PBMCs) or qRT-PCR (lymph node cells) was used to detect viral RNA. In PBMCs, MeV RNA was present primarily in CD20+ B cells up to 60 days after infection (Figure 2B). In lymph nodes, MeV RNA was detectable in CD20+ B cells at 71 days, and at 154 days was also detected in CD3+ and CD14+ (monocyte/macrophages) cells, in addition to CD20+ cells of some animals (Figure 2C). Therefore, B cells were the most frequent, but not the only immune cell in which MeV RNA persisted. MeV RNA was rarely detected in BM mononuclear cells (Table 1).

Development of the MeV-specific antibody response

Dynamics of the MeV-specific antibody response development were characterized through six months after infection (Figure 3). IgM was detectable in plasma by 14 days, reached a maximum at 21 days and decreased by 28 days (Figure 3A). MeV-specific IgG binding and neutralizing antibodies appeared in plasma 2-3 weeks after infection, reached maximum titers
by 21 days and were sustained at elevated levels through 6 months, the last time point tested (Figure 3B). To further define the MeV protein specificity of these antibodies antigen-specific ELISAs for the MeV H, N, and F proteins were performed. All macaques developed antibodies to all three structural proteins (Figure 3C). Antibody responses specific for the N protein were most rapid and abundant, followed by H, and then F and all were sustained for the 6 months evaluated.

Because the quality of the antibody response is important for protection from infection (30), antibody avidity was also assessed. Maturation of the antibody response was slow, as avidity did not peak until 98 days after infection (Figure 3D). At 28 days, when MeV antibody avidity was low, avidity was highest for antibody to the H and N proteins. While avidity of antibody to all evaluated proteins, including F improved later, the highest avidity antibody continued to have specificity for the H and N proteins (Figure 3E) with the mean avidity to H higher higher than to F (mean ±SD: H: 0.964 ± .214 versus F: 0.200 ± .274; adjusted p<0.001)

To further characterize development of the humoral response, we examined the appearance of ASCs in lymph nodes, PBMCs and BM using B-cell ELISpot assays. MeV-specific ASCs were present in lymph nodes 35 days after infection with an increase at 70 days (Figure 4A). In PBMCs, MeV-specific ASCs were detected by 14 days after infection with increases at 3 (27.2 ± 55.3 ASCs/10^6 PBMCs) and 7 (751.5 ± 1070 ASCs/10^6 PBMCs) weeks and continuous entry into circulation for at least 5 months after infection (Figure 4B). During the rash, when MeV-specific ASCs appeared in circulation and began to increase, a 10-fold increase in numbers of total ASCs was also noted (Figure 4B). This increase in total ASCs in relation to baseline and to MeV-specific ASCs was analyzed in more detail in an additional 4 macaques 1-6 weeks after infection (Figure 4C, D). Total ASCs in blood increased 20 to 100-fold 2-3 weeks after infection compared to MeV-specific ASCs, suggesting a general effect of MeV infection on appearance of non-MeV-specific ASCs in the bloodstream during resolution of the rash.
Because BM plasma cells are the source of most plasma antibody (31, 32) we also assessed the appearance of ASCs in the BM at 2-4 week intervals after infection (Figure 4E) for the same animals analyzed in Figure 4B. MeV-specific ASCs were detected by day 14 with an increase 28 days after infection (mean ± SD: 1032 ± 270 ASCs/10^6 BM mononuclear cells) and sustained presence thereafter (Figure 4E). This pattern was confirmed in 3 additional macaques sampled at 14, 35, and 100 days after infection (Figure 4F).

Because antibody to the H glycoprotein is most important for virus neutralization and correlates best with protection from infection (22, 23, 33), we examined the specificity of the antibody produced by ASCs in various compartments for the X monkeys. At day 70, lymph nodes of two animals had equal numbers of H and N-specific ASCs, while the third had more H than N-specific ASCs (Figure 5A). At the same time, ASCs in PBMCs of two animals had equal numbers of H and N-specific ASCs, while the remaining two had more H than N-specific ASCs (Figure 5B). Although H and N-specific ASCs were fairly equally represented in the lymph nodes and blood, analysis of the specificity of the BM ASCs showed an increasing proportion producing antibody to H through 100 days after infection (Figure 5C,D). Therefore, the production of ASCs by lymph nodes with persistent MeV RNA (Figure 2C) resulted in sustained circulation of MeV-specific ASCs through six months after infection with an apparent preferential accumulation of H-specific ASCs in BM (Figure 5).

**Germinal center formation in lymph nodes**

To assess changes in the lymph nodes that harbored MeV RNA (Figure 2) relevant to continuous production of ASCs (Figures 4,5), we compared the morphology in lymph node tissues collected from uninfected macaques to infected macaques at 71-72 and 154-155 days after infection (Figure 6). The presence of germinal centers (GCs), the sites of ASC production, was evaluated by staining sections with hematoxylin and eosin. Infected animals had enlarged reactive lymph nodes and numbers of GCs increased over time (Figure 6A,C).
Immunohistochemical staining showed that Ki67-positive proliferating cells were abundant within GCs at both times after infection (Figure 6B). Ten weeks after infection, there was an average of five GCs within a lymph node section and by 22 weeks the average number of GCs had increased to a variable degree for all 3 animals examined at both time points (Figure 6C), whereas no GCs and few Ki-67-positive cells were identified in lymph nodes from uninfected macaques (Figure 6D).

At 22 weeks, some GCs had become hyalinized, a process by which cells and collagen fibers take on a homogeneous, acellular, “glassy” appearance (Figure 7A,B). The mean number of hyalinized GCs per lymph node increased from <1 at day 71 to approximately 4 at 154 days after infection (Figure 7C) representing an increase in the percentage of hyalinized GCs from a mean of 5% at day 71 to 16.3% at day 154 (Figure 7D). For both numbers of GCs (Figure 6C) and hyalinized GCs (Figure 7 C, D), 14Y had a less dramatic change over time than 17Y and 31Y. One difference of unknown importance is that 14Y received vitamin A at the time of the rash while 17Y and 31 Y did not. Further study of the effect of vitamin A on the immune response to measles may be of interest. Lymph node sections were also stained for CD3+ and CD20+ cells to characterize the distribution of T cells and B cells at day 154 after infection (Figure 7E). CD20+ cells were mainly present in GCs, while CD3+ cells were mostly in the paracortex.

**Peripheral Tfh cells steadily increased after infection**

T follicular helper (Tfh) cells are a subset of CD4+ T cells that play a key role in GC reactions and are essential for B cell proliferation, affinity maturation, and the generation of long-lived memory B cells and antibody-secreting plasma cells (34). In lymphoid tissues, Tfh cells are recognized phenotypically by their expression of CXCR5, ICOS, Bcl-6 and PD-1 and functionally by their synthesis of IL-21 that drives plasma cell differentiation (34-37). While Tfh cells predominantly mediate their function in the lymph node, they are also found in the peripheral
circulation (pTfh cells). Several lines of evidence suggest that circulating CXCR5⁺ CD4⁺ cell populations include memory cells committed to the Tfh lineage that are generated from and share functional properties with GC Tfh cells, but no longer express ICOS or Bcl-6 (38-40). Therefore, we evaluated the expression of CXCR5 on MeV H and N-specific CD4⁺ T cells (Figure 8). H-specific CD4⁺ CXCR5⁺ T cells increased from 0.65% ± 0.28 at 39 days after infection to 2.61% ± 0.69 at 113 days (Figure 8A). N-specific CD4⁺ CXCR5⁺ T cells also increased over time (0.47% ± 0.09 at day 39 to 3.97% ± 1.63 at day 113 after infection).

Next, we examined the co-expression of CXCR5 and PD-1 on MeV-specific CD4⁺ T cells. There was an increase in H- and N-specific CD4⁺ CXCR5⁺ PD-1⁺ T cells over time (Figure 8B, D). However, very little IL-21 production could be detected by intracellular cytokine staining (Figure 8C). Therefore, MeV infection resulted in an increase in MeV-specific circulating pTfh cells for at least four months after infection.
In this study we utilized a rhesus macaque model of primary WT MeV infection to characterize the development of long-lived antibody-dependent protective immunity and the association of this development process with prolonged presence of viral RNA in subsets of immune cells for six months following acute infection. MeV RNA was most consistently detected in B cells in both PBMCs and lymph nodes after clearance of infectious virus but was occasionally detected in T cells and monocytes several months after infection. Infection induced rapid production of MeV-specific antibodies to multiple viral proteins while avidity maturation of the virus-specific antibodies occurred over months. During this period of antibody maturation, lymph node GC B cells proliferated and GCs increased in number. Two to three weeks after infection, MeV-specific pTfh cells and ASCs were detected in blood, with an accompanying burst of circulating ASCs that were not producing antibody to MeV. Although similar numbers of ASCs with specificity for H and N were produced in lymphoid tissue and entered the circulation, ASCs in the BM were more likely to be producing antibody to the H glycoprotein than the N protein.

Together, these data suggest that persistence of WT MeV RNA in lymphoid tissue drives MeV protein production and ongoing antigenic stimulation to promote the progressive development of high quality long-lived plasma cells responsible for the lifelong maintenance of MeV-specific neutralizing antibodies and protective immunity.

WT MeV infects many different types of cells, but cells of the immune system that express the MeV receptor CD150/SLAM are particularly important for systemic spread and for alterations in immunity due to infection (41). Studies of macaques infected with MeV expressing eGFP and of children with measles have shown that MeV infects memory T cells and both memory and naïve B cells during the acute phase of infection (42, 43). Although these populations are transiently depleted during MeV infection, infected immune cells are not eliminated and MeV N gene RNA can be detected in PBMCs for 30-90 days and within the lymph node for at least 6 months after infection (Figure 2C) (8). Sequences from viral RNA
recovered 3-4 months after rash onset are identical to the original infecting virus (10). Thus, although the state of the persistent RNA is unclear the prolonged presence of MeV RNA in tissues is attributable to slow clearance rather than acquisition of escape mutations. In the current study we determined that MeV RNA persists primarily in B cells, but also in T cells and monocytes in PBMCs and lymph nodes, but is rarely detected in BM. However, the nature and intracellular localization of this viral RNA and the time of its eventual clearance are not known. Viral RNA persistence is likely a common feature of acute RNA viral infections (8-10, 44-48) and occasionally leads to reactivation, progressive disease (e.g. subacute sclerosing panencephalitis for MeV) and/or unexpected transmission of infectious virus (e.g. filoviruses, arenaviruses, flaviviruses, alphaviruses) (45, 49-56) months or years after apparent recovery from the acute disease. However, viral RNA persistence may also provide benefit to the host through ongoing synthesis of viral antigens that stimulate progressive maturation of the antiviral immune response to establish long-term protective immunity (11).

Lymphoid tissues are major sites of MeV systemic replication and during the acute phase of measles there is lymphopenia and depletion of cells in lymphoid tissue. This phase is followed by repopulation and proliferation of cells during the appearance of the adaptive immune response and rash (3, 42, 57, 58). In the current study, we have shown that after resolution of the acute rash disease there was a continued increase in formation of GCs and proliferation of B cells in lymphoid tissue for at least six months. This differs from GC formation observed after immunization with soluble protein antigens (59), where GCs are present in draining lymph nodes for only 2-3 weeks. Long-term maintenance of GCs has been observed with chronic viral infections of mice, humans and macaques (59-65) so, although infectious virus is eliminated quickly, persistence of MeV RNA is associated with GC responses similar to those observed with chronic infection. Hyalinization of reactive GCs, observed late after MeV infection, has also been described with chronic infection (61, 66).
There is increasing evidence that the affinity of antibodies induced by infection or immunization is important for protective immunity. For instance, vaccination with inactivated MeV that leads to production of low affinity antibodies is associated with primary vaccine failure and the production of immune complexes and enhanced disease after infection (28, 30, 67). Affinity maturation occurs in GCs through a balance between elimination of lower affinity clones and variants leading to GC homogeneity and loss of clonal diversity (68). This process is facilitated by the ability of follicular DCs to retain antigen for B cell selection and prolonged GC reactions (59, 69). Affinity maturation is dependent on help for B cells within GCs from stromal and Tfh cells producing IL-6, IL-21, APRIL and CXCL12 (34, 36, 70-73). WT MeV infection induced a gradual increase in circulating virus-specific pTfh cells coincident with an increase in antibody avidity and continued production of ASCs. In HIV infection, Tfh cells increase in frequency and serve as cellular reservoirs for replication-competent virus (34, 74), but the ability of these cells to harbor persistent MeV RNA is not known.

During the ongoing development of GCs in secondary lymphoid tissue and affinity maturation of B cells, MeV-specific ASCs were continuously appearing in circulation, presumably trafficking to BM or tissue sites of prior virus infection. This observation during acute MeV infection is in contrast to the response to immunization with a T-dependent antigen or inactivated vaccine where, as with GC formation, ASCs are found in circulation for only 1-2 weeks (75-78). After respiratory syncytial virus infection ASCs have been detected in circulation for up to 2 months (79), but continued virus-specific ASC production for 6 months after an acute infection has not been previously described and likely reflects the continued activation of GCs in lymphoid tissue with persistent viral RNA.

During the first 2-3 weeks after MeV infection with the first appearance of MeV-specific ASCs, 20-100 times as many total ASCs, mostly producing antibody that is not against MeV, also appear in circulation. These cells may represent the non-specific stimulation of memory B cells (80) or the release of plasma cells from a finite number of BM niches to make room for
plasma cells secreting antibody with a new specificity (81, 82). The latter explanation could result in the gradual decline of pre-existing antibody titers and is consistent with the recently observed decrease in diversity of antibody to other pathogens that occurs after measles (83).

ASCs present in the BM are the main contributors to plasma levels of antibody (31, 32) and after measles, ASCs secreting antibody to H were more likely to become established in BM than ASCs secreting antibody to N for all 3 animals examined although similar numbers of H and N-specific ASCs were present in secondary lymphoid tissue for 2 of 3 animals and PBMCs for 2 of 4 animals. It remains unknown whether H-specific ASCs are more likely to express receptors necessary for entering BM niches (e.g. CXCR4) or are more likely to express adhesive integrins or growth factor receptors (e.g. BCMA) necessary for survival as long-lived plasma cells after BM entry (70). Several properties of ASCs facilitate entry into BM niches (70), but antigen-dependent acquisition of these properties may be regulated by affinity maturation that tends to be higher for H than for N or F (84). Most MeV neutralizing antibodies important for protection from re-infection (22) are directed against the H protein (23). Because of variability between animals, further study of larger numbers of animals will be necessary to confirm these observations, but preferential retention of long-lived plasma cells producing antibody to H in BM niches would be advantageous for maintaining protective immunity (85).

In summary, primary WT MeV infection of rhesus macaques resulted in a prolonged induction and maturation of the antibody response that correlated with increasing GC proliferation, production of MeV-specific ASCs and pTfh cells. Thus, the continued presence of MeV RNA in lymphoid tissue is postulated to play a critical role in the maturation of virus-specific immune responses and development of life-long protective immunity, by providing continued antigenic stimulation of both CD4+ T cells and B cells that drive GC formation and continued maturation and production of ASCs.
METHODS

Animals, infection and sample collection

A total of thirteen 2-3 year-old male rhesus macaques (Macaca mulatta) were obtained from the Johns Hopkins Primate Breeding Facility in three groups. The Bilthoven strain of WT MeV (genotype C2; gift of Albert Osterhaus, Erasmus University, Rotterdam, The Netherlands) was grown in phytohemagglutinin-stimulated human cord blood cells and assayed by plaque formation on Vero/hSLAM cells (gift from Yusuki Yanagi, Kyushu University, Fukuoka, Japan). Following baseline measurements, monkeys were infected intratracheally with $10^4$ plaque-forming units of MeV in 1 ml PBS. At the onset of the rash, monkeys in the Y group received either vitamin A (100,000 units, Vitamin Angels, Santa Barbara, CA; 14Y, 50Y) or placebo (17Y, 31Y, 46Y) for two days. No differences have been observed between supplemented and non-supplemented macaques. Y monkeys were analyzed for viremia, RNA persistence, plasma antibody, ASCs in PBMCs and BM, lymph node histology and pTfh cells. A second group of X monkeys (31X, 42X, 46X) had previously received a non-immunogenic experimental sublingual MeV vaccine and were seronegative for MeV at the time of study. X monkeys were analyzed for viremia, RNA persistence, ASCs in lymph nodes and PBMCs. A third group of 5 U/V monkeys (15U, 46U, 67U, 40V, 55V) received no additional manipulation. U/V monkey data for viremia and RNA persistence in PBMCs were previously reported and in this study were analyzed for persistence in T cells. Due to sample availability all assays could not be performed on all animals at all time points. Some data from the Y and U/V experimental groups have been previously reported.

Heparinized blood was collected from the femoral vein before infection and every 3-14 days after infection for six months. PBMCs and plasma were isolated by whole blood gradient centrifugation on Lympholyte-Mammal (Cedarlane Labs). Inguinal lymph node biopsies were
performed 38 and 79 days (31X, 42X, 45X) or 71/72 (14Y, 17Y, 31Y, 50Y) and 154/155 days after infection (14Y, 17Y, 31Y). BM was collected by aspiration from the humerus or femur into a heparinized syringe. For all procedures, monkeys were anesthetized with 10-15 mg/kg ketamine intramuscularly.

Quantification of MeV N gene RNA

MeV RNA in PBMCs and lymph node cells was quantified by qRT-PCR as previously described (8, 88) or by digital droplet (dd) RT-PCR. To analyze individual types of cells, mononuclear cells isolated from PBMCs or LNs were sorted using magnetic beads (Miltenyi Biotec) into CD3⁺, CD20⁺, and CD14⁺ populations. Briefly, for qRT-PCR total RNA was isolated from 2x10⁶ cells and the N gene amplified (Applied Biosystems Prism 7700) using a one-step RT-PCR kit with TaqMan primers (MVN fwd: 5'GGGTACCATCCTAGCCCAAATT-3'; MVN rev: 5'CGAATCAGCTGCCGTGTCT-3') and probe (5'-CTCGAAAGGCAGTTACGGCC). Controls included GAPDH amplification (Applied Biosystems) and RNA isolated from cultured PBMCs from MeV-naïve monkeys. Copy number was determined by construction of a standard curve from 10⁰-10⁸ copies of RNA synthesized by in vitro transcription from a plasmid encoding the Edmonston MeV N gene (MV41 5'-CATTACATCAGGATCCGG-3'; MV42 5'-GTATTGGTCCGCCTCATC-3'). The sensitivity of the assay was 50-100 copies. Data were normalized to the GAPDH control and expressed as [(copies of MeV N RNA)/(copies of GAPDH RNA)] x 5,000.

For ddRT-PCR, the RNeasy Plus Micro Kit (Qiagen) was used to isolate RNA. RNA was eluted in RNase free water and 100 ng used to make cDNA using the iScript™ Advanced cDNA synthesis kit (BioRad, Hercules, CA). A 20 μl mixture of primers, probes, Bio-Rad 2X Supermix (no dUTP) and 5 μl of cDNA was prepared and emulsified with droplet generator oil using a QX-100 droplet generator (Bio-Rad) according to the manufacturer’s instructions. Samples were multiplexed with primers and probes specific for MeV N gene (5' FAM) and GAPDH (5' HEX).
The droplets were then transferred to a 96 well reaction plate (Eppendorf, Hauppauge, NY) and
heat-sealed with pierceable sealing foil sheets (Thermo Fisher Scientific, West Palm Beach, FL). PCR amplification was performed in the sealed plate using a GeneAmp 9700 thermocycler (Applied Biosystems) with the following cycling parameters: 10 min at 95°C, 40 cycles of a 30 sec denaturation at 94°C and a 60 sec extension at 59°C, followed by 10 min at 98°C and a hold at 12°C. Immediately following PCR amplification, droplets were analyzed using a QX100 droplet reader (Bio-Rad). All samples and controls were run in quadruplet. Data are reported as [(copies of MeV N RNA)/(copies of GAPDH RNA)] x 5,000.

**Antibody Assays**

The plaque reduction neutralization test (PRNT) was used to measure neutralizing antibody to MeV. The Edmonston strain of MeV was mixed with serially diluted plasma (1:3 – 1:30,000) and assayed for plaque formation on Vero cells (ATCC). Data are reported as the reciprocal of the serum dilution at which the number of plaques is reduced by 50%.

ELISAs were used to measure MeV-specific IgM and IgG in plasma. 96-well Maxisorp plates (Nalgene Nunc International) coated with lysate from MeV-infected Vero cells (1.16 µg/well; Advanced Biotechnologies) were blocked with 2% non-fat dry milk for 2 h at 37°C. Serially diluted plasma (1:50–1:25,600) was added and incubated at room temperature for 2 h. The secondary antibody was HRP-conjugated goat anti-monkey IgM or IgG (Sigma). Plates were developed using 3,3',5,5'-tetramethylbenzidine as the substrate and the reaction was stopped using 2M H₂SO₄. Plates were read at 450nm. The ELISA titer was the highest dilution at which responses were twice the background.

MeV protein-specific IgG responses were measured using 96-well immunoplates coated with lysates of L cells expressing MeV-H or MeV-F (1:1000), or with baculovirus-generated MeV-N (1:2000) (89, 90). Blocking, serum dilution, IgG detection, and development were performed as above.
To assess the avidity of MeV-specific antibody, ELISAs were performed as described above and following plasma incubation increasing concentrations (0.5M-3M) of ammonium thiocyanate (NH₄SCN) were added for 15 min to disrupt the antigen-antibody interaction. The avidity index was calculated as the concentration of NH₄SCN required to remove 75% of bound antibody (AI₇₅).

**Antibody-Secreting Cells**

Lymph node cells or cells isolated from heparinized blood or BM by density gradient centrifugation with Lympholyte Mammal (Cedarlane Laboratories) were assessed for antibody secretion. Multiscreen HTS HA Opaque plates (Millipore) were coated with MeV-infected Vero cell lysate, H-expressing L cell lysate, baculovirus-expressed N or with purified goat anti-monkey IgG, IgM, IgA (H&L) (Sigma) and incubated at 4°C overnight. After incubation, plates were washed twice with PBS and blocked with RPMI + 10% FBS at 37°C for 1 h. Cells were added to plates and incubated for 6 h at 37°C, 5% CO₂. Samples from lymph nodes and blood were serially diluted and run in 6 wells. Samples from BM were run in 8 replicates without serial dilution. After incubation, plates were washed with PBS-T (1X PBS + 0.05% Tween-20) and bound immunoglobulin was detected with HRP-conjugated goat anti-monkey IgG (Nordic; 1:5000). Plates were developed with stable diaminobenzidine (DAB) solution (Invitrogen) and read on an immunospot plate reader (Cellular Technology). Data were analyzed using Immunospot version 3.0 software. Data are presented as ASCs per 10⁶ cells.

**Histology and Immunohistochemistry**

Inguinal lymph nodes were embedded in paraffin and sectioned. Deparaffinized sections were stained with H & E to assess GCs, Ki-67 (1:100; MM1, Novacastra) to identify proliferating cells, and Masson trichrome to visualize collagenous connective tissue fibers. To characterize immune cell distribution, sections were stained with anti-CD3 (1:400; A052, Dako) or anti-CD20
(1:1000; L26, Dako). Staining was performed using an automated Leica Bond Max system (Leica Biosystems).

**Flow cytometry**

Multicolor flow cytometry with intracellular cytokine staining was used to identify MeV-specific peripheral Tfh cells (CD4+CXCR5+PD-1+). Fresh PBMCs (10⁶ cells per well) were stimulated for 12 h with pooled overlapping H or N peptides (1µg/ml), peptide diluent dimethyl sulfoxide (DMSO; negative control) or staphylococcal enterotoxin B (SEB; positive control). Purified mouse anti-human CD28 (BD Biosciences, CD28.2) and anti-human CD49d (BD Biosciences, 9F10) were included with the peptides or DMSO. All stimulation mixes included protein transport inhibitors GolgiStop and GolgiPlug (BD Biosciences). Live/Dead Fixable Violet Dead Cell Stain Kit (Invitrogen) was used to exclude dead cells from analysis. Prior to surface staining, cells were incubated with a human FcR block (eBioscience) for 10 min on ice. Cells were stained with fluorescently labelled antibodies to the following surface antigens: CD4 FITC (OKT4, Biolegend), CD3 APC-Cy7 (SP34-2, BD Biosciences), CXCR5 PE-Cy7 (J252-D4, Biolegend), and PD-1 PE (EH12.2H7, Biolegend). A “dump channel” was used to exclude CD14+ (PacBlue, M5E2, BD Biosciences) and CD20+ (PacBlue, 2H7, eBioscience) cells. Intracellular staining to detect the transcription factor Bcl-6 (PerCP-Cy5.5, Q21-559, BD Biosciences) and cytokine IL-21 (APC, 3A3-N2, eBioscience) was done following fixation and permeabilization of cells using the Foxp3 Staining Buffer Set (eBioscience). For pTfh phenotyping the following gating strategy was applied: lymphocytes were gated on singlets and live cells were selected to gate on CD3+ cells, followed by gating on CD4+ CXCR5+ cells, which were further phenotyped by gating on PD-1, Bcl-6 and IL-21. Samples were run on a BD FACSDiva and FlowJo software.

**Statistics**
All statistical analysis was performed with GraphPad Prism version 8.0.1. A two-way mixed-effects ANOVA was used for all statistical analyses, post-hoc analyses included a Tukey’s multiple comparisons test. P values less than 0.05 were considered statistically significant. Data are presented as the mean values ± SD.

Study approval

All studies were performed in accordance with experimental protocols approved by the Johns Hopkins University Animal Care and Use Committee.

Author contributions – A.N.N., W-H.W.L. and D.E.G. planned the studies; A.N.N, N.E.P., W-H.W.L, R.S., R.J.A., V.K.B., D.H. and L.M. performed the studies; A.N.N. and D.E.G. wrote the manuscript with input from all authors.

ACKNOWLEDGMENTS

These studies were supported by research grants R21 AI095981 (D.E.G), R01 AI131228 (D.E.G), T32 AI007417 (A.N.N., R.S.) and T32 OD011089 (V.K.B.) from the U.S. National Institutes of Health and by scholarships from the Wisconsin chapter of the Metals Service Center Institute (N.E.P.) and the Marjorie Gilbert Student Scholarship Fund (W-H.W.L.). We are grateful for the assistance of Jane Yeh for lymph node biopsy acquisition.

**Figure 1. Prolonged presence of viral RNA in PBMCs.** Macaques were infected intratracheally with the wild-type Bilthoven strain of MeV. Viremia was measured by cocultivation of serially diluted PBMCs on Vero/hSLAM cells and data from individual macaques are presented as the log (TCID\(_{50}\))/10\(^6\) PBMCs (red lines). MeV N gene RNA in PBMCs was measured by qRT-PCR (black lines). Assays were run in duplicate with a standard of 10\(^1\)-10\(^8\) copies of MeV RNA. MeV RNA load was normalized to GAPDH. Results are expressed as [(MeV N RNA copies)/(GAPDH RNA copies)]*5000.
Figure 2. Detection of MeV RNA in immune cells. Mononuclear cells from peripheral blood (A, B) and inguinal lymph nodes (C) were isolated and assessed for presence of MeV N gene RNA by qRT-PCR (A,C) or ddRT-PCR (B). (A) MeV N gene RNA was quantified in total PBMCs and isolated CD3+ T cells from 4 individual animals (15U, 46U, 67U, 40V). (B) MeV N gene RNA was quantified in quadruplicates by ddRT-PCR in PBMCs collected from Y monkeys between days 14-60 and 75-90 after infection that had been sorted into CD3+ (n=11; n=4, respectively) and CD20 (n=4; n=2 respectively) subsets. (C) MeV N gene RNA was quantified in duplicate by qRT-PCR in lymph node cells collected from Y monkeys 71 and 154 days after infection that had been sorted into CD3+, CD20+ (n=4 at 71dpi) and CD14+ subsets. Numbers of animals studied vary between assays because sufficient cells were not available to perform all assays on all animals. Data are presented as [copies of MeV-N/copies of GAPDH]*5000 for individual animals in dot plots with mean ± SD indicated.
**Figure 3. Antibody production after primary WT MeV infection.** Plasma samples from five Y group macaques were examined for MeV-specific IgM (A) and IgG (B, black line) by enzyme immunoassay (EIA) using MeV-infected cell lysate as antigen. Neutralizing antibody was measured with a plaque reduction neutralization assay using the Edmonston strain of MeV on Vero cells (B, gray line). Dotted vertical lines indicate the period of the rash. (C) Antibodies specific for the H (purple triangle), N (blue circle), and F (green square) MeV proteins were measured by EIA. (D,E) Avidity of MeV-specific IgG was determined by measuring the concentration of NH₄SCN needed to disrupt antigen-antibody interaction. An avidity index 75% (AI₇₅) was calculated for interaction of antibody with MeV (D) and with H, N and F (E) as the concentration of NH₄SCN required to remove 75% of bound antibody. A-D, data presented as mean +/- SD; bar indicates the mean. ***P < 0.001 as determined by 2-way mixed-effects model ANOVA with Tukey’s posthoc analysis.
Figure 4. Prolonged production of antibody-secreting cells. Numbers of MeV-specific or total ASCs present in inguinal lymph nodes (A), PBMCs (B-D) and BM (E, F) at the indicated days after infection were measured by ELISPOT assays. Plates were coated with MeV lysate (MeV-specific ASCs) or anti-monkey IgG, IgA, IgM (total ASCs) and $5\times10^6$ cells were added to each well. All samples were run in duplicate and data plotted number of ASCs for individual X.
group macaques (A, C, D, F) or mean ASCs +/- SD per 10^6 PBMCs (B) or BM mononuclear cells (E) for 5 Y group macaques.

Figure 5. MeV protein specificity of antibody-secreting cells in different compartments.
Relative numbers of IgG-producing ASCs specific for H and N proteins were measured by ELISPOT assays using plates coated with lysates of MeV H-expressing L cells or baculovirus-expressed N protein. Inguinal lymph node ASCs (A) and PBMC ASCs (B) from 3-4 individual macaques were assessed at day 70 after infection. Ratios of H to N-specific ASCs are indicated in red. BM cell ASCs from 3 macaques (31X, 42X, 46X) were assessed 14, 35 and 100 days after infection with data shown as numbers of cells from individual assays (C) and as a ratio of H-specific to N-specific ASCs (D).
**Figure 6. Lymph node germinal center histopathology.** Inguinal lymph nodes biopsies from uninfected macaques and MeV-infected macaques 71 (N=4) and 154 (N=3) days after infection. Tissues were fixed, embedded in paraffin, sectioned, and stained with H&E (A,D) and for expression of Ki67 indicative of cell proliferation (black arrow; B). Representative sections from 14Y (A) and 31Y (B) and an uninfected control macaque (magnification: 4X objective; 10X eyepiece) (D) are shown. Counts of GCs/lymph node section are indicated for 4 MeV-infected macaques from day 71 and 3 MeV-infected macaques from day 154 (C). 50Y data for d154 was not available and the d71 count is superimposed on data from 31Y. Scale bars: 2µm (A: top panels; B: left panel) 100 µm (A: bottom panels; B: right panel)

**Figure 7. Germinal center hyalinization.** Sequential sections from inguinal lymph node biopsies collected 71 and 154 days after infection were stained with H&E (A) and Mason’s Mesenchymal Stain (B). Representative sections from 14Y, 31Y, and 50Y for days 71 and 154 are shown. Counts of hyalinized GCs per lymph node section are indicated for 4 MeV-infected macaques from day 71 and 3 MeV-infected macaques from day 154 (C). Frequency of hyalinized GCs (%) is indicated for 14Y, 31Y, and 50Y for days 71 and 154 (D). Scale bars: 100 µm (A: top panels; B: bottom panels).
Trichrome stain (B) and examined for evidence of GC hyalinization. Representative normal (black arrow) and hyalinized (yellow arrow) GCs from day 154 are indicated. Numbers (C) and percentages (D) of hyalinized GCs/section are graphed for 3 macaques. For 50Y tissue was only available for d71 and no hyalinized GCs were observed. (E) Representative sections from 154 days were stained for CD20⁺ B cells and CD3⁺ T cells. Scale bars: 100 µm.

Figure 8. Circulating peripheral Tfh cells. Frequency of H- and N-specific CD4⁺ CXCR5⁺ (A), CD4⁺ CXCR5⁺PD-1⁺ (B), and CD4⁺ CXCR5⁺IL-21⁺ (C) T cells in the blood at day 39 (n=4), 56 (n= 4), and 113 (n=3) after infection. (D) Representative flow cytometry plots showing co-expression of PD-1 and CXCR5 on H-specific CD4⁺ T cells.
Table 1. Detection of measles virus N gene RNA by ddRT-PCR in BM mononuclear cells from five Y group rhesus macaques.
